#### ABSTRACT

# Proteomic profiling of the cerebrospinal fluid of African Americans and Caucasians reveals common and unique biomarkers of Alzheimer's disease By Erica Modeste

Despite being twice as likely to get Alzheimer's disease (AD), African Americans have been grossly underrepresented in AD research. While emerging evidence indicates that African Americans with AD have lower cerebrospinal fluid (CSF) levels of Tau compared to Caucasians, other differences in AD CSF biomarkers have not been fully elucidated. In this thesis, we performed unbiased proteomic profiling of CSF from African Americans and Caucasians with and without AD to identify both common and divergent AD CSF biomarkers. Multiplex tandem mass tag-based mass spectrometry (TMT-MS) quantified 1,840 proteins from 105 control and 98 AD patients of which 100 identified as Caucasian and 103 identified as African American. Differential protein expression and co-expression approaches were then utilized to assess how changes in the CSF proteome were related to race and AD. Co-expression network analysis organized the CSF proteome into 14 modules associated with brain cell-types and biological pathways. Consistent with previous findings, the increase of Tau levels in AD was greater in Caucasians than in African Americans by both immunoassay and TMT-MS measurements. Similarly, modules enriched with proteins involved with glycolysis and neuronal/cytoskeletal proteins were more increased in Caucasians than in African Americans with AD. In contrast, a module enriched with synaptic proteins including VGF, SCG2, and NPTX2 was significantly lower in African Americans than Caucasians with AD. CSF modules which included 14-3-3 proteins (YWHAZ and YWHAG) demonstrated equivalent disease-related elevations in both African Americans and Caucasians with AD. A targeted mass spectrometry method, selected reaction monitoring (SRM), with heavy labeled internal standards was then used to measure a subset of CSF module proteins and a receiver operating characteristic (ROC) curve analysis assessed the performance of each protein biomarker in differentiating controls and AD by race. Following SRM and ROC analysis, VGF, SCG2, and NPTX2 were significantly better at classifying African Americans than Caucasians with AD. In total, these findings provide insight into additional protein biomarkers and pathways reflecting underlying brain pathology that are shared or differ by race.

CHAPTER 1:

## INTRODUCTION

#### 1.1 The increasing burden of Alzheimer's disease (AD)

Alzheimer's disease (AD) is a progressive and irreversible disorder of the brain that affects memory, thinking, and behavior (1). It is the most common form of dementia, accounting for approximately 60 to 80 % of all dementia cases (2). AD primarily affects older adults, typically starting in individuals over the age of 65 years old (2-6). Notably, the elderly population in the United States has been undergoing rapid expansion since 2011 as the first wave of baby boomers transitioned into the age of 65 (7). The baby boom era, which spanned from 1946 to 1964, marked a distinctive phase in American history characterized by a surge in birth rates following World War II (7). Consequently, with the progression of the baby boomer population from middle to older ages, there has also been a substantial increase in the incidence of AD (7; 8). Up from approximately 4.7 million people in 2010, an estimated 6.7 million people in the United States are currently affected by this disease, and this number is only expected to double by the year 2050 (2; 7; 8) (Figure 1.1). Alongside this rise, there also comes the substantial burden the disease places on caregivers and society (2; 8). In 2022 alone, over 11 million Americans selflessly provided 18 billion hours of unpaid care to older adults afflicted with dementia; a collective contribution valued at nearly \$340 billion (2). Furthermore, total annual payments for healthcare and long-term care for people with AD and other dementias are expected to increase from \$345 billion in 2023 to just under \$1 trillion by 2050, exceeding the costs of treatments for cancer and cardiovascular disease (2; 9). This projection includes three-fold increases in government spending in Medicare and Medicaid, as well as out-of-pocket expenditures (2). Taking into account all of these factors, if there is no progress made in preventing or delaying the onset of AD, coupled with the substantial rise in the number of individuals affected by AD, the proportion of the population impacted by the disease will also increase. This, in turn, will escalate the overall societal burden of AD.

## Figure 1.1: Projected number of people in the United States with Alzheimer's disease (AD)

in millions from 2010 to 2050. The estimated number of people with AD in the United States in 2023 (orange circle) is predicted to nearly double by 2050.

#### 1.2 Monitoring memory loss in those with AD

AD can be most notably recognized by its incapacitating and progressive memory loss. This gradual decline in memory with disease progression is a consequence of spreading neuronal damage across the brain (**Figure 1.2**) (1; 2). Common early signs of memory loss in AD include forgetfulness, difficulty in finding words, misplacing items, and struggling with familiar tasks like tying a shoe (1; 2). As the disease progresses, individuals may begin to experience confusion, mood swings, disorientation, and difficulties in communication and decision-making (1; 2). Ultimately, in the later stages, individuals often require full time care, as they lose the ability to recognize love ones, communicate, and perform basic activities of daily living (1; 2). In the clinic, patients undergo cognitive exams such as the Mini-Mental Status Examination (MMSE) and the Montreal Cognitive Assessment (MoCA). These assessments serve as crucial clinical diagnostic tools for evaluating and monitoring cognitive impairment. (10-12). While the MoCA test is the preferred test for the early detection of dementia such as in cases of mild cognitive impairment (MCI), MMSE is often used for monitoring cognitive decline over time (11; 13).

MCI is an intermediate stage between typical cognitive aging and dementia (11). In the beginning, physicians heavily depended on the MMSE to gauge cognitive impairment in individuals (12). The MMSE was found to be effective in distinguishing cognitively normal individuals from those with cognitive impairment with significant specificity, where a score below 25 on the MMSE was indicative of impairment (12) (**Figure 1.3**). Its efficacy declined, however, when attempting to identify those with MCI, as individuals (14-16) (**Figure 1.3**). This highlighted a significant limitation of the test: its difficulty in detecting early dementia-related changes (17). Consequently, the MoCA test was developed with a heightened emphasis on MCI, while maintaining the scoring ranges of the MMSE (11). Aligned with this, the generally accepted optimal threshold for discerning between individuals with typical cognitive function and those with

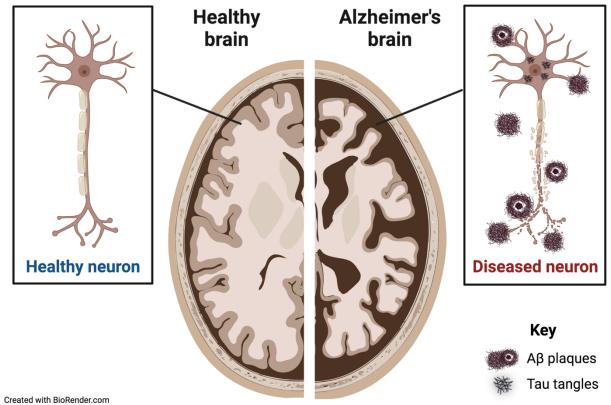

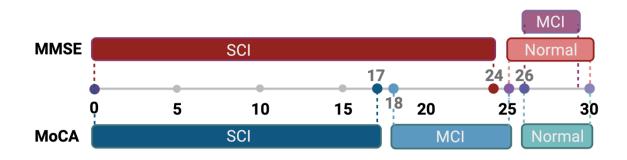

Figure 1.2: Healthy brain compared to a brain affected by Alzheimer's disease. In comparison to a healthy brain, brain changes observed in Alzheimer's disease include injured neuronal cells that are accompanied by abnormal accumulations of amyloid beta ( $A\beta$ ) plaques and tangles of hyperphosphorylated Tau.

Created with BioRender.com

Figure 1.3: A comparison of the scoring patterns of the Mini-Mental State Examination (MMSE) with the Montreal Cognitive Assessment (MoCA).

MCI in the MoCA test was determined to be 26 (11) (**Figure 1.3**). Though, more recent metaanalysis has suggested that a cutoff score of 23 may be better (18). Moreover, individuals with MCI may score between 18 and 25, while those with dementia typically scored below 18 with significant specificity (**Figure 1.3**). Overall, the MoCA test has demonstrated superior effectiveness compared to the MMSE in monitoring the progression from MCI to severe dementia in clinical settings involving living patients (19-22).

There are various factors to consider when utilizing the specified scores mentioned above. Firstly, studies have indicated that education can significantly impact overall MoCA score (11; 23). It was found that persons with 12 years of education or less tended to have worse performance on the MoCA (11). To mitigate this, it has become common practice to add 1 point to the final score for individuals with 12 years or less of education (11). There is debate, however, as to whether this adjustment adequately addresses education-related disparities (24). In some cases, it has been observed that this adjustment may in fact reduce the test's sensitivity (25). Besides education, age can also impact the score (23; 26; 27). This places older individuals with lower levels of education as the group most vulnerable to obtaining false positive results (24). Finally, studies have revealed that MoCA performance can also be influenced by racial background (26; 28; 29). Including minority participants in a study led to lower cutoffs for distinguishing between normal cognition and MCI (26; 28; 29). In addition, when directly comparing optimal MoCA score cutoffs across multiple races, it was found that the optimal cutoff for both African Americans and Hispanics was lower than that of Caucasians (30). This implies that lower MoCA cutoffs may be more appropriate when assessing the MoCA score of minority individuals (26; 28-30). In conclusion, considering factors such as education, age, and racial background is essential for accurately interpreting and applying MoCA scores in clinical settings.

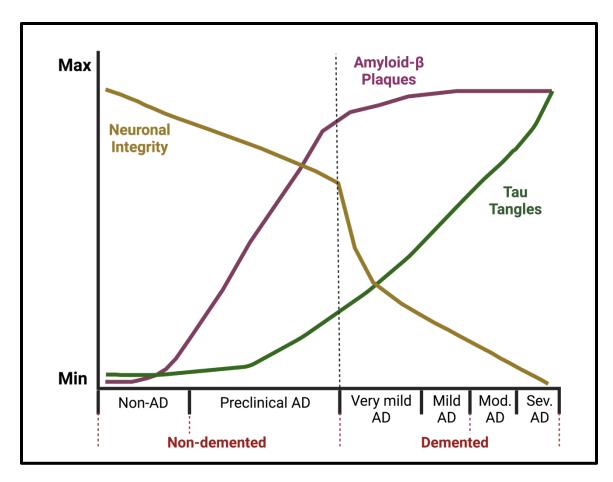

#### 1.3 The initial discovery of AD

Alois Alzheimer was a German psychiatrist and neuropathologist who discovered AD through his work with a patient named Auguste Deter. In 1901, Deter, who was in her early 50s,

was admitted to the mental asylum where Alzheimer worked for exhibiting symptoms of memory loss, confusion, and hallucinations (31). Intrigued by her condition, Alzheimer meticulously documented the continued progression of her disease up until her death on April 6, 1906. Following her death, Alzheimer was able to investigate the brain of Auguste both morphologically and histologically. During the autopsy, Alzheimer noted significant abnormalities in her brain, including unusual protein deposits (now identified as amyloid plaques) and tangled nerve fibers (now known as neurofibrillary tangles) (31; 32). These observations led him to hypothesize that Deter's symptoms stemmed from physical changes in her brain (31). Shortly thereafter, Alzheimer published his findings, presenting the case as a distinct form of dementia that differed from the typical symptoms associated with aging (31). His work laid the groundwork for understanding Alzheimer's disease as a progressive neurodegenerative disorder characterized by cognitive decline and distinct brain pathology. Today, the disease bears Alois Alzheimer's name in recognition of his pioneering research.

#### 1.4 Neuropathological hallmarks of AD

*1.4.1 Amyloid Cascade:* The amyloid cascade hypothesis is a central theory in AD research that proposes that the deposition of amyloid-beta (A $\beta$ ) peptides in the brain occurs prior to and initiates a series of events that culminate in neurodegeneration and the distinctive symptoms of AD (**Figure 1.4**). More specifically, according to this hypothesis, the abnormal accumulation of A $\beta$  peptides leads to the formation of amyloid plaques, which disrupt neuronal function and activate inflammatory responses (33). As a consequence, a cascade of subsequent events is initiated, including the hyperphosphorylation of Tau protein, the formation of neurofibrillary tangles, synaptic dysfunction, and ultimately neuronal death (32). Given its crucial role, the formation and inhibition of A $\beta$  has profoundly shaped investigations into the underlying mechanisms of AD and the creation of potential therapeutic approaches, which primarily focused on A $\beta$  pathways (32; 33). The abnormal accumulation of insoluble A $\beta$  plaques in the extracellular space surrounding neurons has become a hallmark pathology of AD (34; 35) (**Figure 1.2**). A $\beta$  is

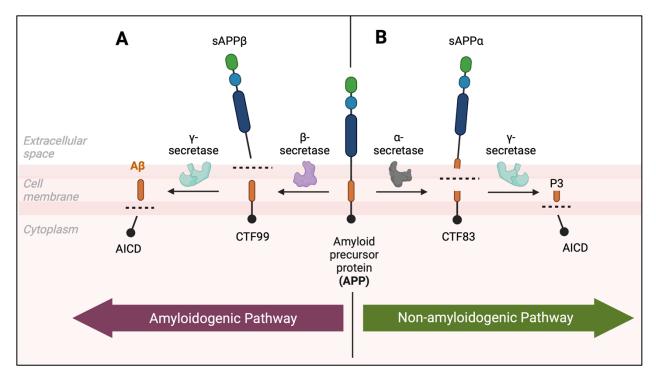

Created with BioRender.com

**Figure 1.4:** Hypothesized time course of neuropathological and clinical changes in **Alzheimer's disease based on biomarker alterations.** In Alzheimer's disease (AD), the conversion from a non-demented to demented state is associated with a buildup of amyloid beta (Aβ) plaques (purple line), a more gradual accumulation of neurofibrillary Tau tangles (green line), and neuronal and synaptic loss (yellow line). Modified from Craig-Schapiro, R., Fagan, A. M., and Holtzman, D. M. (2009) Biomarkers of Alzheimer's disease. *Neurobiol Dis* 35, 128-140.

a peptide ranging from 38-43 amino acids long and is the result of sequential cleavages on amyloid precursor protein (APP) by  $\beta$ -secretase and  $\gamma$ -secretase (36) (**Figure 1.5A**). Initially, APP is cleaved by  $\beta$ -secretase producing a long soluble secreted form of APP (sAPP $\beta$ ) and a Cterminal fragment 99 (CTF99) (37) (Figure 1.5A). Subsequently, CTF99 is cleaved by y-secretase complex to form A $\beta$  and an intracellular amyloid precursor protein intracellular domain (AICD) (38) (Figure 1.5A). This cleavage can produce peptides of 43, 45, 46, 48, 49, or 51 amino acids, which are subsequently processed to generate two forms of A $\beta$ , A $\beta_{40}$  or A $\beta_{42}$  (39). While A $\beta_{40}$  is the most prevalent form,  $A\beta_{42}$  has been noted to be more prominently present in amyloid plaques (40). Because this pathway leads to the formation of the Aß peptides that make up the plaques found in AD, its considered amyloidogenic and is associated with the pathological changes observed in AD. The accumulation of Aβ peptides in the brain is central to the amyloid cascade hypothesis, even though A $\beta$  can be extensively present in the human brain without AD symptoms (36; 41-43) (**Figure 1.4, purple line**). The production of A $\beta$  peptides is not the sole outcome of APP processing. Alternatively, APP can also undergo cleavages that diverts the protein toward a nonamyloidogenic pathway (Figure 1.5B). Here,  $\alpha$ -secretase cleaves APP to release soluble APP $\alpha$ (sAPP $\alpha$ ) and CTF83 (**Figure 1.5B**). Importantly, this pathway prevents the generation of A $\beta$  as the cleavage site for  $\alpha$ -secretase is within the A $\beta$  domain (37).  $\gamma$ -secretase then cleaves CTF83 to form AICD and p3. This neuroprotective pathway promotes neuronal survival, neurite outgrowth and neural stem cell proliferation, providing an avenue for mitigating AD (44-47). Under typical circumstances, these two pathways operate in equilibrium, permitting neurons to remove unnecessary A $\beta$  as required. Nevertheless, in AD, the balance shifts towards heightened A $\beta$ formation, triggering the cascading events described earlier.

1.4.2 Pathologic Tau: The next hallmark of AD is the formation of neurofibrillary tangles (NFT) that consist of hyperphosphorylated microtubule-associated protein Tau (MAPT). Tau is primarily located intracellularly within neurons, but it can also be found in other cell types of the

Created with BioRender.com

Figure 1.5: The amyloidogenic and non-amyloidogenic pathways for processing the amyloid precursor protein (APP). (A) The amyloidogenic pathway involves cleavages by  $\beta$ -secretase and  $\gamma$ -secretase resulting in the generation of a long-secreted form of APP (sAPP $\beta$ ), and C-terminal fragments, CTF99, amyloid precursor protein intracellular domain (AICD), and A $\beta$ . (B) The nonamyloidogenic pathway involves cleavages by  $\alpha$ -secretase and  $\gamma$ -secretase resulting the generation of a long-secreted form of APP, sAPP $\alpha$ , and C-terminal fragments, CTF83, AICD, and P3.

brain, such as microglia (34; 35). In the brain, normal Tau protein plays a crucial role in promoting tubulin assembly and microtubule stabilization. Microtubules are essential structures for maintaining the structural integrity of neurons and facilitating intracellular transport, acting like highways within neurons, allowing molecules and organelles to move to different parts of the cell. Tau protein binds to and stabilizes these microtubules, helping to maintain their structure and function. In addition to this, Tau is also involved in regulating synaptic function, which is essential for communication between neurons. It interacts with various proteins involved in synaptic transmission, contributing to the proper functioning of synapses. Overall, normal Tau protein in the brain is involved in maintaining the structural integrity of neurons by stabilizing microtubules and regulating synaptic function; both of which are critical for normal brain function.

The distinction between normal Tau and pathologic Tau primarily lies in several structural and functional characteristics: conformation, phosphorylation, and aggregation (1). Normal Tau protein is typically structured in a way that allows it to bind and stabilize microtubules within neurons. In contrast, pathological Tau undergoes conformational changes, leading to the formation of abnormal Tau aggregates, such as NFTs (48). In addition to conformational changes, phosphorylation, which is the addition of phosphate groups to proteins, plays a crucial role in deciphering Tau's normal function from that of pathologic Tau. Under normal conditions, Tau is moderately phosphorylated, allowing it to bind and unbind to microtubules effectively. However, in AD, Tau becomes hyperphosphorylated, leading to its detachment from microtubules and the formation of insoluble aggregates (3). Under normal conditions, Tau remains soluble and distributed throughout the neuron, and primarily associated with microtubules. Pathological tau, on the other hand, aggregates into insoluble structures, such as paired helical filaments (PHFs) and NFTs which disrupt neuronal function. These insoluble structures then obstruct transport of essential nutrients and molecules vital for the regular function and survival of neurons (1), making it a more immediate precursor to neurodegeneration (Figure 1.4, green and yellow lines) (49-51).

#### 1.5 The ATN framework for staging AD progression

As defining features of AD, A $\beta$  deposition (A), Tau tangle formation (T), and neurodegeneration (N) make up the basis of the ATN framework (52). Essentially, this framework proposes different sets of biomarkers to represent hallmark pathological features (Aß and Tau) and cognitive aspects (neurodegeneration) of AD, utilizing them to categorize patients along the AD continuum (52). In this framework, amyloid biomarkers represent the earliest indicators of AD neuropathological changes in living persons (53-57). Given this, Aβ biomarkers help determine whether an individual falls within the AD continuum (52). Examples of biomarkers indicative of AB plaques include amyloid positron emission tomography (PET) imaging of radiolabeled ligands binding to AB plaques in the brain and reduced levels of AB<sub>42</sub> in cerebrospinal fluid (CSF) (58-62). The guantification of both Aβ and Tau are required for the diagnosis of AD. Therefore, the presence of pathologic Tau biomarkers is what ultimately determines whether an individual within the AD continuum truly has AD (52). Examples of Tau biomarkers include monitoring elevations in the phosphorylation of Tau at residues Thr181, Thr217, and among other sites (59) within the CSF and PET scans of cortical Tau using radiolabeled ligands that bind to Tau tangles (59; 63-65). Finally, biomarkers of neurodegeneration gauge the severity of neuronal injury. However, these markers do not strictly contribute to the understanding of where a person lies along the AD continuum (52). This is because these markers are not specific to neurodegeneration induced by AD, making it difficult to determine whether neuronal injury is directly attributed to disease or some other comorbid condition (52). Despite this, indicators of neurodegeneration still provide vital staging information when combined with measures of pathologic biomarkers for Aß and Tau (52). Biomarkers of neurodegeneration include total Tau levels in the CSF, cortical PET scans measuring diminished glucose metabolism, and indicators of brain atrophy detected through magnetic resonance imaging (66-73).

#### 1.6 Early-onset AD versus late-onset AD

The majority of people who develop AD are 65 and older. The presentation of AD at older ages is referred to as late-onset AD (LOAD). It is believed that LOAD, like other chronic diseases, is brought on as result of multiple factors, i.e. environmental and genetics, rather than a single genetic cause. The exception to these would-be cases of AD related to uncommon genetic changes that greatly affect risk. In those cases, the person typically develops AD before the age of 65. This presentation of AD at younger ages is referred to as early-onset AD (EOAD). While the greatest risk factors for LOAD are older age, environmental exposures (i.e lifestyle, education, financial attainment), and genetics, EOAD is primarily caused by genetics alone (74-80).

1.6.1 Early-onset AD: EOAD accounts for only ~2 percent of all cases. Individuals who experience familial AD experience rapid decline and die within several years of symptom onset (81). EOAD has been most notably tied to gene mutations that affect the processing or production of A $\beta$ , whose abnormal accumulation contributes to disease. For this reason, despite being on different chromosomes, mutations in *APP*, *PSEN1*, or *PSEN2* are known to cause AD (5; 82-85). Remarkably, both PSEN1 and PSEN2 make up the catalytic components of  $\gamma$ -secretase which assists in the cleavage of APP into A $\beta$ . In addition to these three genetic variants that are known to cause AD, individuals with Down syndrome are often at high risk for developing EOAD (2). This is because they possess an extra chromosome 21, which carries the *APP* gene. Estimates suggests that nearly 50% or more of individuals living with Down syndrome will develop symptoms of AD by their 50s or 60s (86; 87).

1.6.2. Late-onset AD: Contrary to EOAD, LOAD is the most common form of AD, mainly occurring in individuals over 65 (3-6). Also known as sporadic AD, LOAD accounts for the remaining 98% of cases (2; 81). Multiple gene loci have been implicated in LOAD. As a result, LOAD is often considered a polygenic disorder (2). One of the most impactful genetic susceptibilities to LOAD involves the Apolipoprotein E gene (5; 88; 89). Apolipoprotein E (APOE) epsilon ( $\epsilon$ ) protein has three different variants that differ at residues 112 and 158: APOE  $\epsilon$ 2

contains a cysteine at both resides 112 and 158 while APOE  $\varepsilon$ 3 contains a cysteine at residue 112 but an arginine at residue 158. Lastly, APOE  $\varepsilon$ 4 has two arginine residues that occupy position 112 and 158 in the full-length protein. Those who inherit a copy of the *APOE*  $\varepsilon$ 4 allele have three times the risk of developing AD while those who inherit two copies have an eight- to 12-fold risk (90-92). Contrastingly, the inheritance of the *APOE*  $\varepsilon$ 3 allele has no risk of developing AD while the *APOE*  $\varepsilon$ 2 offers some protection. Although genetic studies support that *APOE* is the largest modifier of an individual's risk of developing LOAD, half of the individuals with LOAD do not possess an *APOE*  $\varepsilon$ 4 allele indicating that other loci influence LOAD development. Innovations in genomic sequencing technology have allowed for the identification of other genetic polymorphisms linked to AD through genome wide association studies (GWAS). Such genes include genes that encode for proteins involved in the dysregulation of microglia (CD33, SHARPIN, TREM2),  $\alpha$ -secretase (ADAM10, ADAM17, TSPAN14), endocytosis (BIN1, PICALM, WDR81), the lysosome (CTSB, CTSH, IDUA, TMEM106B), and sorting receptors (SORL1, SORT1, SNX1) (93; 94). More genes are expected to be revealed as genomic studies continue to expand and grow in sample size and ethnic background.

#### 1.7 Risk factors for AD

1.7.1 Age: The most significant contributor to AD risk is age (2; 74). This is evident by the steep increases in the percentage of people with AD with advancing age. For example, five percent of individuals between 65 and 74 years old have AD which then increases to 13.1 % for those aged from 75 to 84 (95). By the time one reaches 85, this number doubles, affecting 33.3% of this population range (95). It is worth highlighting again that these prevalence statistics are projected to steadily increase as the baby-boom generation continues to move throughout these age ranges (8; 95). Although age plays a major role in risk, AD is not a natural outcome of the aging process; in other words, simply reaching an older age is not adequate enough to trigger the onset of AD (96).

1.7.2 Sex: Approximately two-thirds of AD patients are women (97). While men have only a 1 in 10 chance of developing AD, women's likelihood is twice as high, 1 in 5 (95). Although it has been speculated that women's heightened risk of developing AD could be due to their longer lifespan, studies indicate that differences in several biological factors such as sex hormones, immune response, and metabolic regulation can modulate risk (98). One significant factor affecting risk is the sex hormone, estrogen. Estrogen receptors are distributed throughout the brain, regulating various physiological processes, some of which exert protection against AD pathology. Studies show that estrogen achieves this protective effect by stimulating the generation of vesicles containing APP from the Golgi network (99; 100). This mechanism then facilitates the transport of APP to the cell surface where, it either undergoes cleavage by  $\alpha$ secretase, yielding the soluble and neuroprotective molecule, sAPP $\alpha$ , or is re-internalized through an endosomal/lysosomal degradation pathway (101-103). Both of which precludes the production of insoluble Aß peptide (99-104). Additionally, estrogen has been shown to decrease the presence of hyperphosphorylated Tau and increase the presence of dephosphorylated of Tau (105). In the perimenopausal phase, however, which occurs 1-4 years prior to menopause, estrogen levels fluctuate significantly. This variability contributes to dysfunction in metabolic, inflammatory, and sensory-processing pathways associated with estrogen (106; 107). Consequently, the eventual loss of estrogen during menopause contributes to females' susceptibility to AD (108; 109). In contrast, men do not undergo an equivalent of perimenopause. Instead, they experience a gradual decline in testosterone (110). This gradual transition elucidates the age-related dysfunction in male hormonal pathways compared to those in females (110).

#### 1.8 Modifiable risk factors for AD

1.8.1 Role of modifiable risk factors in AD: Although age and sex cannot be changed, some risk factors can be modified to reduce the risk of cognitive decline and dementia without relying on a cure or medicine (111). In fact, studies suggest that addressing modifiable risk factors may prevent or delay up to 40% of all dementia cases (112). Notably, nearly a third of cases of

AD and other dementias in the United States are associated with at least one of eight modifiable risk factors: physical activity, smoking, depression, low education, diabetes, midlife obesity, midlife hypertension, and hearing loss (113). Of these, the greatest factors to AD risk have been shown to be midlife obesity, physical inactivity, and low educational attainment (113).

Timing also holds significant importance in relation to modifiable risk factors in that the age in which these risk factors develop affects the impact on AD risk. For example, developing obesity, hypertension, and high cholesterol during midlife can elevate one's risk of dementia in later stages of life (114-120). For example, those between 40 and 79 years old lacking a number of modifiable risk factors (low education, hypertension, hearing loss, traumatic brain injury, alcohol or substance abuse, diabetes, smoking and depression) have been shown to exhibit cognitive performance akin to individuals 10-20 years younger with multiple modifiable risk factors (121). Conversely, the onset of obesity and hypertension in late life, after the age of 80, is associated with a reduced risk in dementia (122; 123). Moreover, addressing modifiable risk factors during midlife was connected to decreased dementia risk, even among individuals with a heightened genetic predisposition to dementia (124). In essence, while genetic inheritance is unalterable, exerting an influence on cognitive function becomes feasible by avoiding modifiable risk factors.

1.8.2 Cardiovascular health: The interdependence between brain health and cardiovascular health has been recognized for a considerable time. This connection is likely rooted in the fact that, despite accounting for just 2% of the body's weight, the brain utilizes approximately 20% of the body's oxygen and energy resources. In this context, a healthy heart is crucial for facilitating adequate blood supply to the brain, while healthy blood vessels ensure the delivery of oxygen and nutrient-rich blood to this vital organ. As a result of this intricate relationship between brain and cardiovascular health, many factors that increase the risk of cardiovascular disease are also associated with a higher risk of dementia (125). Notably, these factors encompass conditions such as hypertension and diabetes (114; 116; 118; 119).

1.8.3 Smoking / physical activity / diet: Due to the close relationship between cardiovascular health and brain function, behaviors that impact the heart's well-being can also influence the brain, thereby affecting the risk of developing dementia. Not surprisingly, smoking has been associated with an elevated risk of dementia (126), whereas engaging in physical activity has been shown to decrease risk (127-136). Now despite extensive exploration into various forms of physical activity, determining the specific types, frequencies, and durations that yield the most significant reduction in risk remains an ongoing challenge. In addition to physical activity, emerging evidence suggest that adhering to a heart-healthy diet could decrease one's risk of dementia (137-142). A heart-healthy diet places emphasis on fruits, vegetables, whole grains, fish, poultry, nuts, legumes, and beneficial fats such as olive oil while simultaneously limiting the intake of saturated fats, red meat, and sugar (2).

#### 1.9 Social determinants of health

Historically, the healthcare sector bore the primary responsibility for addressing health and disease concerns, as it was widely recognized for its role in delivering care to those most in need (143). However, it's increasingly evident that medical care alone is not sufficient to improve health outcome or mitigate health disparities (144). In fact, research suggests that differences in life expectancy and disease prevalence among various demographics are largely shaped by the conditions in which individuals are raised, live, work, and age (143). These nonmedical factors, encompassing socioeconomic status, educational attainment, job opportunities, social support networks, healthcare accessibility, and the quality of the physical environment, profoundly influence health outcomes and overall well-being, and are collectively referred to, today, as social determinants of health (143). Some of these factors that most notably affect disease risk include education, employment, income, environment, discrimination and exposure to stress.

1.9.1. Education: Education can improve health by increasing health knowledge and healthy behaviors (144). In support of this, higher educational attainment has been linked to engaging in health-promoting behaviors and adopting health-related recommendations earlier

(145; 146). This could partially be attributed to literacy (147; 148). It is believed that literacy enables individuals with higher education levels to make more informed health-related decisions for themselves and their families (147; 148). Education also holds significance in health by influencing employment opportunities (144). Higher levels of education are associated with reduced unemployment rates, a factor strongly correlated with poorer health and increased mortality (149). Similarly, individuals with higher educational attainment are more inclined to hold positions offering healthier physical working environments, superior health-related benefits, and higher compensation (150; 151). Lastly, education may also affect health by influencing social and psychological factors where higher education levels have been correlated with heightened perceived personal control, a factor frequently associated with improved health outcomes and health-related behaviors (145; 147). In summary, higher levels of education are associated with improved health outcomes because education equips individuals with the knowledge and ability to make healthier choices, to obtain secure employment conducive to better access to healthcare, and to exercise greater personal control over their health.

1.9.2. Employment: The physical aspects of work can have clear impacts on health (144). For instance, occupations involving repetitive movements and/or high physical demands increase the likelihood of workers experiencing muscular or skeletal injuries and disorders (152). Similarly, individuals with sedentary jobs who are physically inactive face elevated risks of obesity and chronic diseases such as diabetes and heart disease (153). Besides physical factors, the psychosocial aspects of work also have an impact on health (144). Psychosocial factors refer to the circumstances wherein a person's social environment, cultural norms, interpersonal relationships, and overall well-being shapes their mindset and behavior. For instance, employees in roles marked by high demands coupled with low control or perceived imbalance of efforts and rewards face an increased risk of experiencing poor health (154; 155). Those who are socially disadvantaged frequently contend with lower wages or income and are typically the ones most likely to confront these health-harming physical and psychosocial conditions in their workplaces

(156). In conclusion, both the physical and psychosocial aspects of work play crucial roles in determining individuals' health outcomes, with socially disadvantaged groups often bearing a disproportionate burden of these adverse conditions, further exacerbating health disparities.

Work can also affect health through the opportunities and resources it provides (144). In general, for most Americans, earnings from employment constitute their primary economic resource. Consequently, health can be influenced by employment-related benefits such as medical insurance, paid leave, flexible scheduling, workplace wellness initiatives, resources for child and elder care, and retirement benefits (144). Positions with higher salaries are likelier to provide benefits, increased financial security, and the means to afford healthier living environments (144). On the flip side, those categorized as the working poor generally earn inadequate income to meet basic needs and are less likely to have access to health-related benefits (157; 158). In summary, the opportunities and resources available through employment significantly impact health outcomes. While higher salaries often come with benefits and financial security conducive to healthier living, those who are poor often face challenges accessing basic necessities and health-related benefits. This underscores how the socioeconomic impacts of employment can contribute to disparities in health.

1.9.3 Environment: There are many characteristics of one's environment and neighborhood that can influence health (144). Regarding physical characteristics, the quality of air and water, along with the accessibility of nutritious foods and safe exercise spaces, can collectively influence an individual's health (159-165). For example, exposure to pollutants, unsafe living conditions, and limited access to green spaces can contribute to respiratory problems, injuries, and chronic diseases such as cardiovascular diseases. In addition to the physical characteristics, the availability and quality of the services a neighborhood offers could also influence health. Services such as schools, transportation, medical care and employment resources can influence health by shaping individuals' opportunities to earn a living (166-168). Interestingly, neighborhood features can be linked to health even when considering individuals

within the same neighborhood (169). Remarkably, some researchers have found poorer health among disadvantaged individuals living in relatively advantaged neighborhoods (170-172). This could be largely due to the adverse psychological effects of feeling worse off than one's neighbors, the perception of having weaker social ties to other residents in the neighborhood, or even having increased exposure to discrimination (173). In conclusion, the environment, or neighborhood, in which one lives plays a significant role in shaping an individual's health outcomes. Beyond the physical aspects such as air and water quality and access to nutritious foods and safe exercise spaces, the availability and quality of neighborhood services also exert considerable influence. Surprisingly, even within the same neighborhood, disparities in health outcomes can persist, highlighting the complex interplay of social and psychological factors. As we continue to explore these dynamics, it becomes increasingly clear that addressing health disparities requires a multifaceted approach that considers not only physical environments but also social and economic factors.

1.9.4 Stress: Coping with daily challenges can be particularly taxing, especially when an individual's financial and social resources are restricted (144). Recent evidence suggests that, in fact, chronic stress connects many social determinants of health and likely plays a causal role in their effects on health (174; 175). Stressful experiences, such as those associated with social disadvantage, like economic hardship and racial discrimination, triggers the release of cortisol, cytokines, and other substances that can damage immune defenses, vital organs, and physiologic systems (174; 176-179). Subsequently, this harm contributes to the accelerated onset or advancement of chronic conditions, such as cardiovascular disease, and the physical toll from chronic stress may hasten the aging process (175; 180-182). In fact, evidence suggest that the accumulated strain from repeatedly attempting to cope with daily challenges, especially with limited resources, may actually cause more physiological damage than a single significantly stressful event would (180). In conclusion, the intricate relationship between chronic stress and health emphasizes the urgent need for comprehensive interventions that address the systemic

inequities contributing to daily challenges. This highlights the increased significance of allocating resources and establishing support systems to address health disparities.

1.9.5 Discrimination and social exclusion: In the United States and many other societies, race or ethnic group is another important social factor that influences health, primarily because of racism (144). It's important to note that the associations between discrimination and health are not uniquely observed in the United States and has been also observed in other countries (178). Racism encompasses not only explicit, intentional acts and beliefs of discrimination, but also entrenched societal systems that, even without explicit discriminatory intent, systematically limit the opportunities and resources available to certain individuals based on their race or ethnic background (144). Racial segregation in residential areas is a critical mechanism by which racism generates and sustains social disadvantage (168; 183). African American and Hispanic individuals are more prone to living in underprivileged neighborhoods characterized by poorly equipped schools, leading to lower educational achievement and guality, which can result in health consequences through the pathways outlined earlier (184). Racism can also have a more direct impact on health by triggering chronic stress. Persistent stress resulting from encounters with racial or ethnic bias, including subtle instances lacking overt prejudicial intent, can potentially contribute to health inequalities based on race or ethnicity, regardless of one's neighborhood, income, or educational attainment (178; 185). In fact, research suggests that African Americans and Hispanic Americans with more education or income are exposed to more discrimination than those who are disadvantaged (144). Acknowledging the widespread impact of racial or ethnic bias on health outcomes underscores the imperative of addressing systemic inequities to achieve genuine health equity.

1.9.6 Final conclusions: Ultimately, insufficient and unequal living conditions arise from flawed social policies, unfair economic structures, and ineffective governance (143). As a result, tackling the social determinants of health necessitates a holistic approach involving government at various levels, civil society, local communities, businesses, international organizations, and

global initiatives (143). Consequently, policies and programs designed to enhance health outcomes must encompass all sectors of society, rather than solely concentrating on healthcare (143). Collaboration among these sectors is crucial for implementing policies and programs that address the root causes of health disparities, especially across racial and ethnic background.

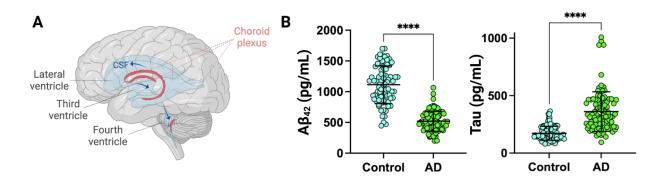

#### 1.10 Therapeutic attempts to slow the progression of AD

Despite decades of research, we still have no disease modifying treatment and no cure. Although the clinical symptoms of AD are frequently diagnosed in older age, the degenerative process of AD can begin many years prior to disease onset where individuals can remain cognitively normal for 10-20 years despite accumulating pathology (Figure 1.4) (186-188). Given this, AD has remained an elusive disease to treat and cure. Current treatments available mainly alleviate the cognitive deficits associated with AD. Cholinesterase inhibitors, such as galantamine, rivastigmine, donepezil, and memantine, have remained routine treatment options for the symptomatic relief of mild to moderate AD. Drugs such as these were first implemented to combat the theory that the loss of acetylcholine (ACh) neurons is to blame for the cognitive deficits observed in AD (189). Similarly, declines in nicotinic ACh receptors and M2 muscarinic ACh receptors have been shown to be responsible for AD progression (190; 191). Overall, these treatments have remained ineffective in removing the root of AD pathogenesis, merely targeting symptoms so as to only temporarily improve a patient's cognitive outcome. Consequently, it has become a critical goal of AD research to develop drugs that target the underlying mechanisms and processes involved in the progression of AD. Such therapies would aim to modify the course of the disease by reducing the build-up of Aβ plaques and Tau tangles, which are hallmarks of AD pathology. For this reason, immunotherapeutic strategies such as Aβ-directed immunotherapy dominated the AD research for its potential to directly target the plaques associated with disease. Passive immunotherapies, such as bapineuzumab and ALZ 801, relied on the direct injection of monoclonal antibodies into the patient's body, utilizing the immune system to increase clearance of pathologic Aß fragments (192). Remarkably, recent amyloid immunotherapy treatments

lacanemab and donanemab were found to not only reduce amyloid burden in the brain but also moderately slow cognitive decline (193; 194). Despite this, however, they were unable to reverse the neuronal loss and cognitive impairments observed in advanced stages of AD (193-196). This failure has been attributed to the initial treatment being administered at too advanced stage of AD in which neuronal damage is severe (195; 197; 198). Thus, it has become a prioritization of AD research to shift towards the early detection and or prevention of AD (52).

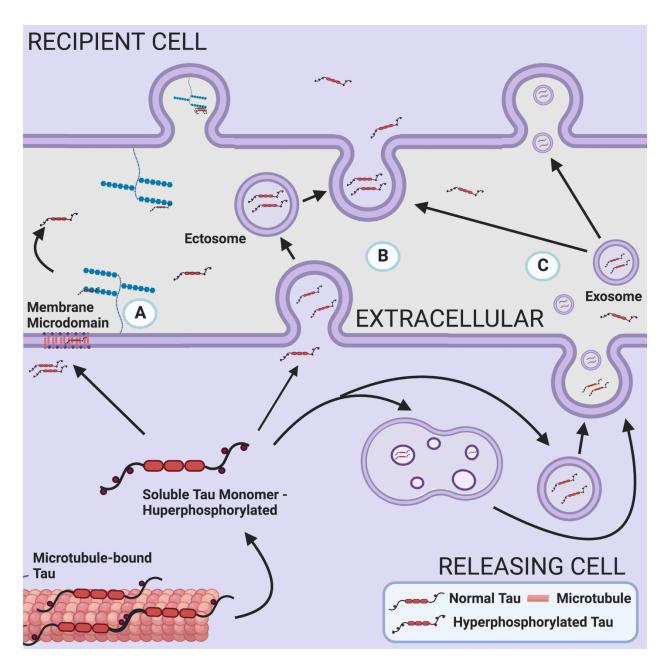

#### 1.11 Cerebrospinal fluid (CSF) as a gateway to neuropathological changes in AD

CSF has become a promising source of biomarkers for the early detection and monitoring of AD in living patients. CSF is made by highly vascularized tissue within the ventricles of the brain called choroid plexus (199). Once created, CSF flows from the lateral ventricles to the third and fourth ventricles, and then into the subarachnoid space and spinal cord (Figure 1.6A). This direct contact with the brain gives CSF, removed via lumbar puncture from the spinal cord, the ability to reflect neuropathological changes in the brain of living patients (200). More specifically, decreases in AB and elevations in Tau in the CSF have been shown to distinguish healthy controls from AD (201) (**Figure 1.6B**). Decreases in A $\beta$  in the CSF is thought to be the result of increases in accumulations of Aβ into plaques in the brain which have been largely found to be the result of the impaired clearance of A $\beta$  out of neurons during disease (202). Interestingly, only a fraction of Tau found in the CSF is due to the passive release of Tau from dying cells (203). Markedly, increasing levels of Tau in the CSF are predominantly the result of the enhanced secretion or release of Tau from the intracellular regions of neurons into the extracellular space. In fact, studies have shown that Tau hyperphosphorylation may be critical for its secretion (Figure 1.7). For example. studies have shown that Tau can be secreted at the synaptic terminal during normal synaptic activity (204; 205). Tau hyperphosphorylation, however, can enhance its secretion at the synaptic terminal as hyperphosphorylated Tau has been shown to be preferentially secreted during both ectosome shedding and exosome fusion (Figure 1.7B & C) (204; 206). Moreover, unlike normal physiological Tau, hyperphosphorylated Tau can also be secreted directly across

Figure 1.7. Methods by which pathological Tau can be secreted or released into extracellular space. (A) Tau can be actively secreted through the plasma membrane. (B) Tau can be released by ectosome shedding from the plasma membrane. (C) Tau can be packed into exosomes by inward budding and become secreted by of multivesicular bodies along the plasma membrane. Modified from Brunello, C. A, Merezhko, M., Uronen, R., and Huttunen, H. J. (2019) Mechanisms of secretion and spreading of pathological tau protein. *Cellular and Molecular Life Sciences*. <u>https://doi.org/10.1007/s00018-019-03349-1</u>

the plasma membrane (**Figure 1.7A**) (207; 208). While the exact mechanism by which Tau is secreted into the CSF is unclear, it remains evident that the CSF of AD patients displays changes in Tau composition and that these changes, particularly that of phosphorylated Tau species, significantly correlate with neocortical NFT pathology in the brain (209). Together, these changes observed in CSF biomarkers, A $\beta$  and Tau, give physicians the ability to determine individuals at risk of developing AD and researchers the ability to use CSF as a tool for assessing biological processes reflective of early disease stages (210).

#### 1.12 African Americans: the most at-risk racial group for AD

African Americans are almost twice as likely to have AD compared to Caucasians (211-213). Current evidence suggests that this difference in risk could be explained by a multitude of factors including genetic ancestry and disparities in health, socioeconomic and environmental conditions (214-217). For example, GWAS show that the ABCA7 gene has stronger associations with AD risk in individuals with African ancestry than in individuals with European ancestry (216; 217). ABCA7 also has a stronger effect size in African Americans than even the strongest genetic risk factor gene for AD, the APOE s4 allele (216). Yet, despite the APOE s4 allele being more prevalent amongst African Americans, APOE £4 confers a lower risk for AD compared to Caucasians (76). Beyond genetic ancestry, chronic health conditions associated with higher risk for dementia, such as cardiovascular disease and diabetes, also disproportionally affect African Americans (214; 215). Furthermore, societal and environmental disparities that disproportionately affect African Americans, including lower levels and quality of education, higher rates of poverty, and greater exposure to adversity and discrimination, increase risk for both chronic diseases and dementia (214; 215). This highlights how racial differences in AD risk cannot be explained by genetics alone (214). Currently there is a gap in knowledge of the racial differences in underlying pathophysiology related to AD. Therefore, a better understanding of these mechanisms can help move towards a more precise definition of AD across diverse racial, ethnic, and genetic

backgrounds. An unbiased analysis into the CSF proteome of African Americans could provide insight into additional biomarkers reflecting underlying brain pathology that differ by race in AD.

# 1.13 The utility of mass spectrometry (MS)-based proteomics in identifying novel protein signatures in AD

1.13.1 Strategies for MS-based quantification of proteomes: Proteomic analyses of AD brain have predominantly utilized "bottom-up" mass spectrometry (MS) for protein identification and quantification. This workflow generally involved enzymatic digestion of proteins with trypsin, followed by protein separation via liquid chromatography (LC), and subsequent measurement of protein peptides using tandem mass spectrometry (MS/MS) (218). The first stage of measurement (MS1) involves the selection of several precursor peptides for fragmentation. The fragmented peptides are then identified through spectral matching and quantified using well-established statistical and informatic methods during the second stage of tandem MS (219-224). In summary, the "bottom up" approach to MS has become a cornerstone in the comprehensive analysis of proteomic profiles in AD research. Since then, significant advancements have been made to enhance protein identification and quantification, resulting in more detailed proteomic profiles.

Over the years technological strategies have further improved this workflow by enhancing the quantification and depth of proteomic datasets. Initially, label-free quantification (LFQ) was the preferred technique. Using this technique, each sample is individually prepared and analyzed using LC-MS/MS. Since each sample is analyzed individually, a limitation of this technique is that the peptides selected and analyzed can vary significantly between samples. This is due to the inherent nature of MS1 where peptide selection is biased toward the most intense signals (225). When trying to quantify proteins that are lost in a disease, this means that a protein quantified in a healthy state may be completely absent in the disease state and therefore not quantified. This results in a well-documented "missing value" problem, ultimately reducing the number of proteins retained in an LFQ dataset (225-228). Multiplex isobaric peptide labeling with tandem mass tags (TMTs) helps address the issue of missing values by allowing the simultaneous analysis of

multiple samples within a single LC-MS/MS run, currently accommodating up to 16 samples per run (229; 230). When combined with off-line fractionation, this strategy can quantify thousands of additional proteins compared to LFQ, which has enabled remarkably deep proteomic analysis of AD brain tissue (227; 228; 231; 232). A study that came out of the Seyfried Lab, Johnson et al., demonstrated this advantage in one of the first TMT-MS network proteome studies of the AD brain. This study quantified 6,533 proteins across 47 brain tissues compared to just 2,736 proteins quantified by LFQ-MS using the same samples (227). Despite these advancements in quantification, TMT-MS may still produce missing values across multiple batches which occurs when analyzing large numbers of samples (233). Targeted approaches such as selected reaction monitoring (SRM) can serve as a mitigate for the limitation of "missing values" by utilizing its ability to identify nearly all detectable peptides within a selected mass range. This allows for comprehensive and accurate quantification of the identified proteins in the sample with minimal to no missing values. This method is often used in research settings for more robust quantification of pre-specified individual peptides (234). Utilizing a targeted approach like this can be useful in validating discovery-driven data that results from tandem MS, as it requires specifying a target beforehand. In conclusion, the evolution of technological strategies, from LFQ to multiplex isobaric peptide labeling and targeted approaches like SRM, has significantly enhanced proteomic workflows, enabling comprehensive and accurate quantification of proteins.

1.13.2 Fundamentals of network construction and module identification: Unbiased proteomics of human brain coupled with network analysis has emerged as a valuable approach for organizing complex proteomic data into groups or "modules" of co-expressed proteins that reflect various biological functions (227; 235-237). Co-expression network analysis operates on the premise that proteins react to biological stimuli as a "system," altering expression collectively within groups or "modules" of a network. Effectively organizing proteomic datasets into the described co-expression protein modules requires a thoroughly validated statistical algorithm. One such extensively validated algorithm, commonly employed in transcriptomic studies, is

Weighted Gene Co-expression Network Analysis (WGCNA) (235; 238-241). This algorithm applies graph theory principles to detect modules of proteins exhibiting highly correlated abundance levels across samples. Through evaluating the connectivity of each protein within a module, researchers can identify module-specific hubs or proteins that play central roles in module function. Typically, the most centrally connected proteins in a module serve as key drivers (238; 240; 242). Module-level abundance profiles can then be correlated with various phenotypic traits of the disease, such as amyloid burden, tangle deposition, and cognitive decline (243). These module-trait correlations reveal protein groups with strong positive or inverse relationships to the disease. In addition to module-trait correlations, module enrichment profiles can also provide important insights into proteomic composition. This analysis seeks to identify the overrepresentation of module proteins linked to specific cell types, biological functions, or genetic risk factors. It accomplishes this by cross-referencing the proteins within a module with well-validated databases. For instance, cell type enrichment is usually conducted by comparing module proteins with marker lists from established reference proteomes or transcriptomes of purified murine brain cells (218; 227; 228). In addition to cell enrichment lists, numerous resources are available for pathway and ontology analysis. Go Elite is a versatile analytical tool that enables users to incorporate both reference and custom databases to investigate ontological over-representation at biological, molecular, and organellar levels (244). Altogether, network analysis offers the ability to resolve the complex nature of disease by utilizing mathematical and computational tenets of system biology which results in the formation of communities (modules) of proteins, which can be representative of phenotypes that arise out of the molecular pathophysiology of disease.

1.13.3 Why prioritize the study of the proteome over the genome: Proteins are the ideal markers for understanding diseases such as AD because they are most proximal to the phenotypic changes seen in AD. Protein-level analysis offers the advantage of revealing disease-related changes that are not easily detectable in transcriptomic networks. Notably, only 30-40% of the modules in the AD brain network proteome overlap with those in the network transcriptome.

(235; 245). Furthermore, despite the fact that differential protein expression within these overlapping modules has been found to exhibit a reasonable degree of concordance, with a correlation coefficient of approximately 0.5, it has been repeatedly observed that the targets within the most concordant modules across transcriptomics and proteomics exhibit highly discordant changes at the protein and RNA levels (235; 245; 246). These discrepancies highlight the complexity and non-linear relationship between the transcriptome and proteome, stressing the importance of the numerous events that occur from the initial transcription of DNA to the point when a protein performs its function. This also aligns with the observation that only half of the disease-related variance in the AD network proteome is mirrored in transcriptome-level gene expression, while the remaining 50% results from transcriptional and post-translational effects (246). These findings align with previous comparisons of protein and mRNA data (237), and strongly supports the value of protein profiling in AD research, highlighting the unique aspects of proteomic changes that can only be achieved through protein analysis.

1.13.4 Core modules of the AD brain network proteome: Nearly a dozen comprehensive network-based analyses of the AD proteome in the human brain have led to the identification of six highly conserved modules, each with reproducible associations to specific cell types, organelles, and biological functions (217; 221; 225; 226; 235-241). Several modules, such as inflammatory, myelination, and RNA binding/splicing, consistently showed increases in the AD brain network proteome, while others, like synaptic, mitochondrial, and cytoskeleton, displayed consistent decreases. Notably, some of these modules (inflammatory, myelination, synaptic, and mitochondrial) appear to be driven by cell-type-specific perturbations (226), while those lacking such enrichment (RNA binding/splicing and cytoskeleton) represented underlying biochemical changes associated with the disease. The complexity of the modules preserved in AD confirms the multifactorial nature of the condition, which has led to inherent challenges in understanding AD and, consequently, in developing effective interventions.

1.13.5 The CSF proteome as a reflection of AD brain changes: The close proximity of CSF to the brain, along with its ability to reflect changes in amyloid burden and neurodegeneration through markers like AB and Tau, provides a compelling rationale for integrating the CSF proteome with the brain proteome. Furthermore, the reflection of other AD pathophysiologies in the CSF would provide additional avenues for detecting and monitoring treatment responses, especially at earlier stages of disease. Our first attempt to validate this interaction via proteomics was based on findings by Johnson et al., which identified that approximately 20 proteins from the highly conserved microglial module showed significant elevations in AD CSF (237). This provided the initial evidence necessary to explore this interaction more deeply. In another large-scale study by the Seyfried lab, Higginbotham et al. used a similar integrative proteomic approach to examine the statistical overlap between the entire AD brain network proteome and differentially expressed proteins in the AD CSF proteome (245). Notably, fifteen of the 44 brain modules identified in this study showed a strong overlap with the markers differentially expressed in AD CSF. Collectively, those 15 modules from the brain were being represent by 300 proteins that were significantly altered in AD CSF compared to controls. Based on their corresponding brain modules, these approximately 300 CSF AD targets were then segregated into five biomarker panels that represented a wide range of brain pathophysiology. These panels included synaptic transmission, vascular biology, myelination, glial-mediated inflammation, and energy metabolism. The panels highlighting brain changes in AD that could potentially be monitored through CSF. This comprehensive approach highlights the potential of CSF proteomics to uncover diverse aspects of AD pathology and to enhance the precision of biomarker-based diagnosis and therapeutic monitoring.

### 1.14 Summary

Evidence of differences in AD biomarkers between African Americans and Caucasians exists yet the underrepresentation of African Americans in research means data to support such alterations is lacking. This demonstrates a greater need for broad investigations into the

underlying biological differences of AD in African Americans as a means to identify AD biomarkers that are representative of and generalizable across diverse racial, ethnic, and genetic backgrounds. Including participants from diverse racial backgrounds ensures that research findings are more representative of the entire population and can be generalized to different racial and ethnic groups. Without this, there lies a risk of bias and limited applicability of research outcomes to specific populations. The following research will demonstrate how an integrated proteomic and network approach can be utilized to comprehensively define the proteomic profiles of AD within individuals of African American or Caucasian background. We hypothesize that the biological pathways most relevant or impacted by changes in Tau burden will demonstrate varying expression levels in the CSF of African Americans and Caucasians with AD. Through a combination of unbiased system level and target approaches, I have been able to (i) directly characterize CSF within a large cohort of individuals (ii) gain insight into race-specific molecular signatures of AD and (iii) validate novel race-dependent signatures for AD pathogenesis using an independent mass spectrometry technique. In total, there is a significant gap in our knowledge of the racial differences underlying molecular mechanisms of AD biology. A better understanding of these mechanisms is critical to move the field towards clearer biological methodologies for the early detection of AD across a diverse population of people.

# CHAPTER 2:

## MATERIALS AND METHODS

This Materials and Methods was originally published in *Molecular Neurodegeneration*:

Modeste, E.S., Ping, L., Watson, C.M. *et al.* Quantitative proteomics of cerebrospinal fluid from African Americans and Caucasians reveals shared and divergent changes in Alzheimer's disease. *Mol Neurodegeneration* **18**, 48 (2023). <u>https://doi.org/10.1186/s13024-023-00638-z</u>

A full list of tables can be accessed at the following link:

#### 2.1 CSF samples

All cerebrospinal fluid (CSF) samples were collected as part of ongoing studies at Emory's Goizueta Alzheimer's Disease Research Center (ADRC) including participants in the ADRC Clinical Core, the Emory Healthy Brain Study, and the ADRC-affiliated Emory Cognitive Neurology Clinic. All participants provided informed consent under protocols approved by Emory University's Institutional Review Board. Clinical diagnosis of AD as well as classification as cognitively normal controls was based on review of clinical history, neurological examination, detailed cognitive testing, and diagnostic studies including Magnetic Resonance Imaging and CSF AD biomarker testing. Diagnosis of AD was made by subspecialty certified Cognitive and Behavioral Neurologists with additional input from Neuropsychologists based on current NIA-AA criteria (247; 248). A consensus clinical diagnosis of controls was made without consideration of CSF biomarkers by a panel of experts at the Emory Goizueta ADRC. Criteria for assigning diagnosis are provided in the National Alzheimer Coordination Center coding guidelines, form D1, based on clinician judgment. The basis for this judgment includes many metrics, with controls considered to have normal cognition and normal behavior after reviewing all testing including Montreal Cognitive Assessment (MoCA), Clinical Dementia Rating (CDR) score, and detailed neuropsychological testing. Hence, control participants may have MoCA scores that are lower than traditional cut points for impairment on this screening test. CSF was collected by lumbar puncture and banked according to best practice guidelines outlined by the National Institute on Aging for Alzheimer's Disease Centers (https://alz.washington.edu/BiospecimenTaskForce.html), and identical pre-analytic steps were followed in all groups. Measurements of Amyloid-beta<sub>1-42</sub> (Aβ<sub>42</sub>), total Tau (tTau), and phosphorylated Tau<sub>181</sub> (pTau<sub>181</sub>) was performed on the Roche Diagnostics Elecsys platform (249-251) using recommended protocols. In total, the cohort was comprised of 105 healthy controls and 98 AD. The racial background of each case was based upon self-identification. Of the 203 cases, 100 identified as Caucasian or White while 103 identified as African American or Black. Case metadata can be found in Appendix Table 6.1.

#### 2.2 Protein digestion of CSF

In order to sample the CSF proteome in an unbiased manner and given that we have previously shown that immunodepletion resulted in only a marginal improvement in proteomic coverage, the CSF samples were not immunodepleted prior to digestion (252; 253). First, 70 μL of CSF was transferred to 1 mL deep well plates for digestion with lysyl endopeptidase (LysC) and trypsin. The samples were then reduced and alkylated with 1.4  $\mu$ L of 0.5 M tris-2(carboxyethyl)-phosphine (ThermoFisher) and 7 µL of 0.4 M chloroacetamide in a 90°C water bath for 10 min. The water bath was then turned off and allowed to cool to room temperature along with samples for 5 minutes. Following this, water bath sonication was performed for 5 min. The samples were then allowed to cool again to room temperature for 5 mins prior to adding urea. Then 78 μL of 8M urea buffer (8M urea, 10mM Tris, 100mM NaH<sub>2</sub>PO<sub>4</sub>, pH 8.5) and 3.5 μg of LysC (Wako), was added to each sample, resulting in a final urea concentration of 4M. The samples were then mixed well, gently spun down, and incubated overnight at 25°C for digestion with LysC. The following day, samples were diluted to 1M urea with a blend of 468 µL of 50 mM ammonium bicarbonate (254) and 7 µg of trypsin (ThermoFisher). The samples were subsequently incubated overnight at 25°C for digestion with trypsin. The next day, the digested peptides were acidified to a final concentration of 1% formic acid and 0.1% trifluoroacetic acid. This was immediately followed by desalting on 30 mg HLB columns (Waters) and then eluted with 1 mL of 50% acetonitrile (ACN) as previously described (228). To normalize protein quantification across batches, 100 µl was taken from all CSF samples and then combined to generate a pooled sample. This pooled sample was then divided into global internal standards (GIS) (255). All individual samples and the pooled standards were then dried using a speed vacuum (Labconco).

#### 2.3 Tandem mass tag labeling of CSF peptides

All CSF samples were balanced for diagnosis, race, age, and sex (in that order) across 16 batches using ARTS (automated randomization of multiple traits for study design) (256). Using a 16-plex Tandem Mass Tag (TMT) pro kit (Thermo Fisher Scientific, A44520, Lot number: VH3111511), 13 channels of each batch were allocated to a CSF sample (127N, 127C, 128N, 128C, 129N, 129C, 130N, 130C, 131N, 131C, 132N, 132C, 133N). The remaining 3 channels were occupied with a GIS pool (126), a standard biomarker negative pool (133C), and a standard biomarker positive pool sample (134N). Information regarding the origination of these pooled samples were reported previously (257). **Appendix Table 6.2** provides the sample to batch arrangement. In preparation for labeling, each CSF peptide digest was resuspended in 75  $\mu$ l of 100 mM triethylammonium bicarbonate buffer meanwhile 5 mg of TMT reagent was dissolved into 200  $\mu$ l of ACN. Once both were in suspension, 15  $\mu$ l of TMT reagent solution was subsequently added to the resuspended CSF peptide digest. After 1 hour, the reaction was quenched with 4  $\mu$ l of 5% hydroxylamine (Thermo Fisher Scientific, 90115) for 15 min. Then, the peptide solutions were combined according to the batch arrangement. Finally, each TMT batch was desalted with 60 mg HLB columns (Waters) and dried via speed vacuum (Labconco).

#### 2.4 High-pH peptide fractionation

Dried samples were re-suspended in high pH loading buffer (0.07% vol/vol NH<sub>4</sub>OH, 0.045% vol/vol FA, 2% vol/vol ACN) and loaded onto a Water's BEH column (2.1 mm x 150 mm with 1.7 µm particles). A Vanquish UPLC system (ThermoFisher Scientific) was used to carry out the fractionation. Solvent A consisted of 0.0175% (vol/vol) NH<sub>4</sub>OH, 0.01125% (vol/vol) FA, and 2% (vol/vol) ACN; solvent B consisted of 0.0175% (vol/vol) NH<sub>4</sub>OH, 0.01125% (vol/vol) FA, and 90% (vol/vol) ACN. The sample elution was performed over a 25 min gradient with a flow rate of 0.6 mL/min with a gradient from 0 to 50% solvent B. A total of 96 individual equal volume fractions were collected across the gradient. Fractions were concatenated to 48 fractions and dried to completeness using vacuum centrifugation.

#### 2.5 Mass spectrometry analysis and data acquisition

All samples (~1µg for each fraction) were loaded and eluted by an Easy-nLC 1200 (Thermofisher Scientific) with an in-house packed 15 cm, 150 µm i.d. capillary column with 1.7 µm CSH (Water's) over a 35 min gradient. Mass spectrometry (MS) was performed with a high-field asymmetric waveform ion mobility spectrometry (FAIMS) Pro front-end equipped Orbitrap Lumos (Thermo) in positive ion mode using data-dependent acquisition with 1 second top speed cycles for each FAIMS compensative voltage. Each cycle consisted of one full MS scan followed by as many MS/MS events that could fit within the given 1 second cycle time limit. MS scans were collected at a resolution of 120,000 (410-1600 m/z range, 4x10^5 AGC, 50 ms maximum ion injection time, FAIMS compensative voltage of -45 and -65). Only precursors with charge states between 2+ and 5+ were selected for MS/MS. All higher energy collision-induced dissociation MS/MS spectra were acquired at a resolution of 50,000 (0.7 m/z isolation width, 35% collision energy, 1×10^5 AGC target, 86 ms maximum ion time). Dynamic exclusion was set to exclude previously sequenced peaks for 30 seconds within a 10-ppm isolation window.

#### 2.6 Database search and protein quantification

All raw files were analyzed using the Proteome Discoverer Suite (v.2.4.1.15, Thermo Fisher Scientific). MS/MS spectra were searched against the UniProtKB human proteome database (downloaded in 2019 with 20338 total sequences). The Sequest HT search engine was used to search the RAW files, with search parameters specified as follows: fully tryptic specificity, maximum of two missed cleavages, minimum peptide length of six, fixed modifications for TMTPro tags on lysine residues and peptide N-termini (+304. 304.2071 Da) and carbamidomethylation of cysteine residues (+57.02146 Da), variable modifications for oxidation of methionine residues (+15.99492 Da), serine, threonine and tyrosine phosphorylation (+79.966 Da) and deamidation of asparagine and glutamine (+0.984 Da), precursor mass tolerance of 10 ppm and a fragment mass tolerance of 0.05 Da. Percolator was used to filter peptide spectral matches and peptides to a false discovery rate (FDR) <1%. Following spectral assignment, peptides were assembled into proteins and were further filtered based on the combined probabilities of their constituent peptides

to a final FDR of 1%. Peptides were grouped into proteins following strict parsimony principles. A complete TMT reporter ion abundance-based table output of assembled protein abundances without adjustments can be found at <a href="https://www.synapse.org/EmoryDiversityCSF">https://www.synapse.org/EmoryDiversityCSF</a>.

#### 2.7 Adjustment for batch and other sources of variance

Only proteins quantified in  $\geq$  50% of samples were included in subsequent analysis (n = 1,840 proteins). Of the 1,840 proteins, 1,327 proteins were quantified across all samples. As previously reported (236; 237; 252; 258), batch correction was performed using a Tunable Approach for Median Polish of Ratio, (https://github.com/edammer/TAMPOR), an iterative median polish algorithm for removing technical variance across batch. Multidimensional scaling plots (MDS) were used to visualize batch contributions to variation before and after batch correction. Noticeably, prior to batch correction, cases within the same batch clustered together and batches ran consecutively tended to cluster more closely together (Figure 2.1A). Following batch correction using a median polish algorithm, the cases were no longer clustering by batch (Figure 2.1B). The data was then subjected to outlier removal using a robust principal component analysis method, *PcaGrid* (259). A scree plot graphing the eigenvalue against the principal component (PC) number was utilized to determine the number of PCs to include in the parameters (Figure 2.1C). Briefly, the parameters used for outlier detection were as follows: the desired number of principal components = 7, method = mean absolute deviation, and criterion for computing cutoff values = 0.99 (Figure 2.1D). This resulted in the detection and removal of 15 outliers, resulting in a final n=189 samples. Bootstrap regression was then performed to remove for covariates such as age at collection and sex. Variance partition analysis was performed to confirm appropriate regression of these traits (Figure 2.1E & F). Since the variancePartition package does not allow missing values, proteins with missing quantifications were temporarily imputed using the impute.knn function of the impute R package. The final cleaned dataset after regression and log2 transformation can be found at https://molecularneurodegeneration.biomedcentral.com/articles/10.1186/s13024-023-00638-z.

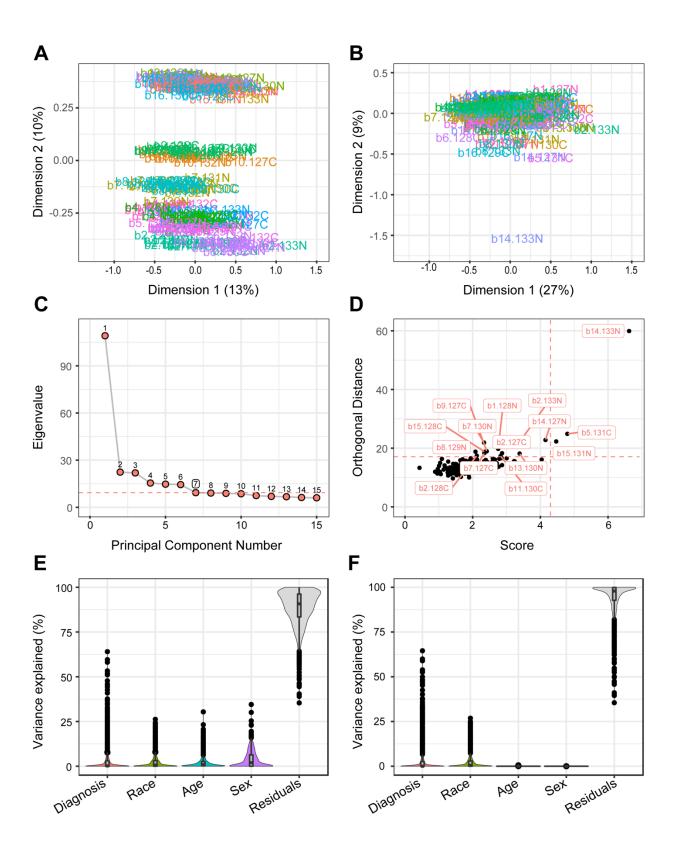

Figure 2.1: Batch correction, outlier removal and bootstrap regression. Multidimensional scaling plots (MDS) were used to illustrate batch contributions to variance before and after batch correction. In MDS plots, the distance a case is from one another is reflective of how similar or dissimilar a case is from the other. (A) Prior to batch correction, the samples clustered by batch (B) After batch correction, the samples no longer cluster by batch. (C) After batch correction, a principal component (PC)-based outlier removal method was utilized to detect outliers. By graphing the eigenvalue of each component against the PC number, the elbow or bend in the graph, which in this case was 7, was indicative of the ideal number of components to include within the parameters. (D) With a criterion for computing cutoff values set to 0.99, the cutoffs for the detection of outliers for the orthogonal distance and score were 16.79257 and 4.654674 respectively. This resulted in the detection of 15 outliers (b1.128N, b11.130C, b13.130N, b14.127N, b14.133N, b15.128C, b15.131N, b2.127C, b2.128C, b2.133N, b5.131C, b7.127C, b7.130N, b8.129N, b9.127C). B14.133N was such an extreme outlier because it was an empty channel. (E) After outlier removal, the matrix underwent bootstrap regression to remove variations in the dataset that were due to age and sex. Variance partition plots were employed to illustrate the percent contribution of diagnosis, race, age, and sex to the variance of each protein. (F) Following bootstrap regression, variations explained by age and sex were removed.

#### 2.8 Differential expression analysis

One-way ANOVA followed by Tukey's post hoc adjustment for multiple comparisons was performed on four groups (Control-Caucasian, Control-African American, AD-Caucasian, and AD-African American) to identify differentially expressed proteins across diagnosis and within each race. Differentially expressed proteins for comparisons of interest (i.e., Control-Caucasian vs AD-Caucasian and Control-African American vs AD-African American) were then presented as volcano plots using the *ggplot2* package in R v4.1.2. A list of all comparisons computed with corresponding adjusted p-values is provided in **Appendix Table 6.3**.

#### 2.9 Weighted Gene Co-expression Network Analysis

As previously published (235-237; 252), the blockwiseModules function from the WGCNA package in R was utilized to derive the weighted protein co-expression network. Briefly, the following parameters were used: soft threshold power beta = 3, deepSplit = 4, minimum module size = 5, merge cut height = 0.07, and a signed network with partitioning about medoids. Using the *pairwise.wilcox.test* R function with Bonferroni correction, a pairwise Wilcox test was performed to calculate pairwise comparisons between each group with corrections for multiple testing.

#### 2.10 Gene ontology and cell type enrichment analysis

To characterize co-expressed protein module biology, gene ontology (GO) annotations were retrieved from the Bader Lab's monthly updated .GMT formatted ontology lists downloaded July 5, 2022 (260). A Fisher's exact test for enrichment was performed into each module's protein membership using an in-house script (<u>https://github.com/edammer/GOparallel</u>). For cell type enrichment analysis, an in-house marker list was used as previously described (236). A Fisher's exact test was performed for each module member list using the merged human cell type marker list to determine cell type enrichment. For brain-CSF module overlap a one-sided Fisher's exact test to compare significance of module membership.

#### 2.11 Selected reaction monitoring

Selected reaction monitoring (SRM) assays were performed on 195 of the 203 cases to determine whether a separate targeted proteomic approach could replicate proteomic changes seen in TMT discovery proteomics. An attempt was made to include all 203 samples from discovery TMT for SRM analysis however, samples 52524, 51520, 52055, 48617, 48615, 48769, 49537, 45707 had low remaining sample volume and had to be removed. Sample 62762 was later removed due to irregularities in retention time shifts. Peptide selection, sample preparation, peptide quantification, and data acquisition for the SRM assay was performed as previously described (257). Briefly, peptides were selected based on their robust detection and significant differential expression in previous CSF discovery proteomic projects for synthesis as heavy standards (237; 252). More specifically, the peptide had to i) have one or more spectral matches, ii) be significantly differentially abundant when evaluating AD versus Control cases, iii) and map to proteins that appeared in brain-based biological panels outlined in Higginbotham et al 2020 (252) that differed in AD. Ultimately, this led to approximately 200 peptides being nominated for synthesis by Thermo Fisher Scientific (Thermo PEPotec SRM Peptide Libraries; Grade 2; crude as synthesized). In addition to the 195 clinical samples from before, two pools of CSF were utilized as AD biomarker positive and AD-biomarker negative quality controls (QC) standards (257). After the CSF samples were blinded and randomized, each sample (50 µL) was reduced, alkylated, denatured and then subjected to digestion as described (257). After digestion, the heavy labeled standards, 15uL per 50 µL of CSF, were added to each digested sample. Each digested sample then underwent acidified, desalted and dried under vacuum. Following this, the peptide targets were quantified using TSQ Altis Triple Quadrupole mass spectrometer as previously described (257). The resulting raw files were uploaded to Skyline-daily software (version 21.2.1.455) for peak integration and quantification by peptide ratios. Peptides were filtered by first assessing retention time reproducibility, then by matching light and heavy transitions, and finally by determining the peptide ratio precision using the coefficient of variation (CV) as described by

Watson et al 2023 (257). The technical CV of each peptide was calculated based on the peptide area ratio for the AD-positive and AD-negative QC pools (Appendix Table 6.4). CSF peptide targets with  $CVs \le 20\%$  in at least one pooled standard were determined as peptides with high precision and were kept for subsequent analysis, leaving a total of 85 peptides that mapped to 58 proteins. The total area ratio for each targeted peptide in each sample made up the final data matrix. Due to the nature of SRM in that each peptide is explicitly targeted, a value for each peptide is always assigned in each sample (down to and including the limit of detection) as previously published by our group (257). As a result, the total area ratio for each targeted peptide in each sample made up the final data matrix, leaving a matrix with no blank cells or missing values. In preparation for analysis, this matrix of peptide ratios was log<sub>2</sub> transformed and true zero values were replaced after log<sub>2</sub>-transformation with the minimum value for that peptide minus 1. Bootstrap regression was then used to regress for age and sex (Appendix Table 6.5). Bicor was then utilized to calculate the correlation between SRM peptides and TMT-MS protein measurements (Appendix Table 6.6). In cases where multiple peptides mapped to one protein, the most correlated peptide was kept for further analysis (Appendix Table 6.7). One-way ANOVA analysis with Tukey adjustment was then utilized once again to examine pairwise interactions (Appendix Table 6.8) and receiver operating characteristic (ROC) curve analysis was performed as previously described (257) (Appendix Table 6.9).

# **CHAPTER 3: RESULTS**

These Results were originally published in *Molecular Neurodegeneration*:

Modeste, E.S., Ping, L., Watson, C.M. *et al.* Quantitative proteomics of cerebrospinal fluid from African Americans and Caucasians reveals shared and divergent changes in Alzheimer's disease. *Mol Neurodegeneration* **18**, 48 (2023). <u>https://doi.org/10.1186/s13024-023-00638-z</u>

A full list of tables can be accessed at the following link:

https://molecularneurodegeneration.biomedcentral.com/articles/10.1186/s13024-023-00638-z

#### 3.1 CSF cohort characteristics

This study was comprised of two balanced groups of cerebrospinal fluid (CSF) samples from African American and Caucasian individuals, matched for age and sex with roughly equal numbers of control and Alzheimer disease (AD) cases (Table 3.1). This included 53 Caucasian controls, 52 African American controls, 47 AD Caucasians, and 51 AD African Americans. The majority were female and on average the controls (64.5 years) were slightly younger than AD (68 years). Notably, there were no statistical differences between the ages of the African Americans and the Caucasians within diagnosis (control: p=0.8848, AD: p=0.9998). As expected, AD cases had lower Montreal Cognitive Assessment (MoCA) scores than controls, but there were no statistically significant differences between MoCA scores across race within controls and AD (control: p=0.7559, AD:p=0.2055). The AD cases also had lower Amyloid-beta (A $\beta_{42}$ ) levels and elevated total Tau (tTau) and phosphorylated Tau<sub>181</sub> (pTau<sub>181</sub>) levels. Notably, A $\beta_{42}$  levels were significantly lower in African American Controls compared to Caucasian controls (p = 0.0021) but not different between African American AD and Caucasian AD. This may indicate potentially early changes in brain amyloid deposition or processing of APP in African American controls versus Caucasian controls. Notably, the distribution of APOE4 carriers did not differ significantly by race in the control population and so does not account for the pattern observed (Appendix Table 6.1). Conversely, tTau and pTau<sub>181</sub> levels were significantly lower in African Americans with AD (tTau:p<0.0001, pTau<sub>181</sub>:p<0.0001) but not different between African American and Caucasian controls. Data on comorbid conditions, including whether or not the person had hypertension, diabetes, dyslipidemia, or cerebrovascular disease, is presented for all cases in Appendix Table **6.1.** Notably, none of the comorbid conditions was statistically overrepresented in either racial group.

Sample Size	CT Cau	CT AA	p – value ª	AD Cau	AD AA	p – value <sup>a</sup>

# 3.2: Discovery tandem mass spectrometry analysis of cerebrospinal fluid from African Americans and Caucasians reveals unique and shared changes in Alzheimer's disease

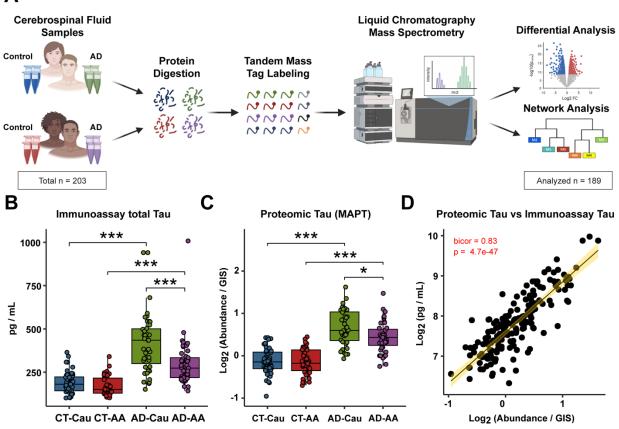

3.2.1 Correlation analysis uncovers a strong relationship between mass spectrometry and immunoassay measurements of Tau

Following enzymatic digestion, tandem mass tag (TMT) labeling, and off-line fractionation, all samples were subjected to liquid chromatography mass spectrometry (MS) (**Figure 3.1A**). In total, TMT-MS proteomic analysis identified 34,330 peptides mapping to 2,941 protein groups across the 203 samples (16 total batches). To account for missing protein measurements across batches, we included only those proteins quantified in at least 50% of samples following outlier removal as previously described (227; 235-237; 252), resulting in the final quantification of 1,840 proteins. Protein abundance was adjusted for batch and age and sex were regressed. As expected, Tau levels were significantly elevated in both African Americans and Caucasians with AD across both platforms compared to controls (**Figure 3.1B and C**). Consistent with the immunoassay measurements, TMT-MS Tau levels also showed significantly lower levels in African Americans with AD compared to Caucasians with AD (**Figure 3.1C**). Notably, protein levels of Tau (MAPT) by TMT-MS correlated strongly to independently measured tTau levels via immunoassay (r=0.83, p = 4.7e-47) (**Figure 3.1D**). Thus, in this study, both platform measures of CSF Tau support a reduction of total Tau levels in African Americans with AD, consistent with previous findings (261; 262).

3.2.2 Differential expression analysis of African American and Caucasian CSF proteome reveals unique and shared changes in AD

Differential expression analysis was performed to identify changes in the CSF proteome by race in AD (**Appendix Table 6.3**). Consistent with previous proteomic analyses of AD CSF (237; 252; 263-265), there was a significant increase in Tau (MAPT), 14-3-3 proteins, (YWHAZ, YWHAG, and YWHAE), SMOC1, neurofilaments (NEFM and NEFL) and proteins involved in

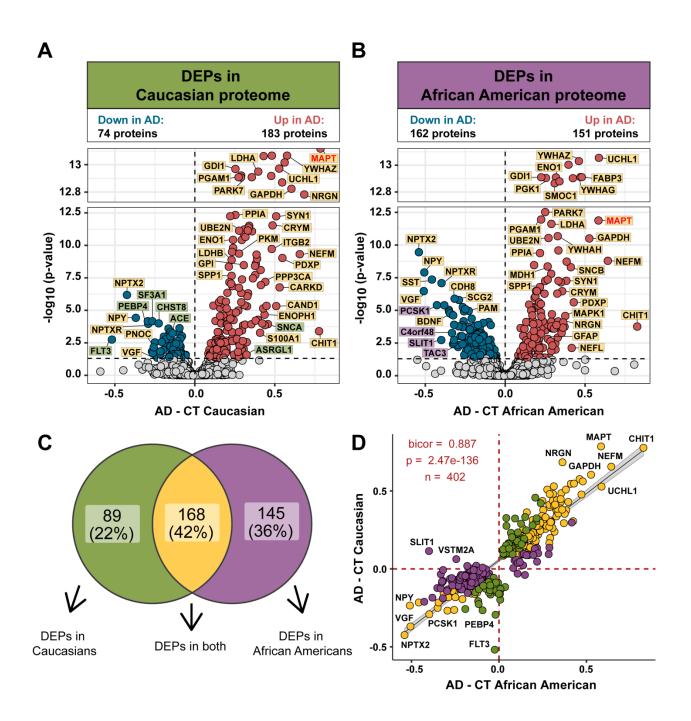

Part A of this figure was created with BioRender.com

**Figure 3.1:** Schematic of experimental workflow and correlation between proteomic Tau and total Tau immunoassay measurements. (A) Schematic of experimental workflow for quantification of cerebrospinal fluid proteome. (B) Total Tau levels as measured by Roche Elecsys Platform between control (CT) and AD cases and stratified by self-identified race: Caucasian (Cau) or African American (AA) (C) Tau levels measured by mass spectrometry. Oneway ANOVA with Tukey post-hoc correction determined pairwise relationships (D) Correlation of Tau levels by TMT-MS (x-axis) to paired immunoassay total Tau levels (y-axis). Biweight midcorrelation coefficient (bicor) with associated p-value is shown. Only 179 cases were included in the linear regression analysis because of sample outlier removal and missing values in the TMT-MS. glucose metabolism in both African Americans and Caucasians with AD compared with race matched controls (**Figure 3.2A & B**). However, Caucasians with AD exhibited a bias towards proteins that were increased in AD, where the number of differentially expressed proteins (DEPs) was nearly double (n=183 proteins) the number of decreased DEPs in AD (n=74 proteins) (**Figure 3.2A**). In contrast, in African Americans, the number of increased and decreased DEPs was more balanced (151 increased proteins vs. 162 decreased proteins) (**Figure 3.2B**). A Venn diagram illustrates the overlap of DEPs from African Americans and Caucasians with AD (**Figure 3.2C**), with the majority of proteins (n=168 proteins) differentially expressed in both races. Furthermore, a correlation analysis of both shared and unique DEPs showed overall high agreement in direction of change (bicor=0.887, p=2.47e-136, **Figure 3.2D**). However, there were some exceptions including SLIT1 and VSTM2A, which were significantly increased in Caucasians, but decreased in African Americans with AD. Both proteins are predominantly enriched in neuronal-cell types (266; 267). Thus, despite the differences in the number of significant DEPs in African Americans compared to Caucasians with AD, the direction of change with disease remains largely similar across both races.

3.2.3 Network analysis of the CSF proteome reveals modules related to pathways and brain celltypes

Co-expression network analysis of the AD brain proteome organizes proteins into modules related to molecular pathways, organelles, and cell types impacted by AD pathology (227; 235-237). Moreover, integration of the human AD brain and CSF proteome revealed that approximately 70% of the CSF proteome overlapped with the brain proteome (252). While proteomic networks in AD brain have been examined, network changes in the AD CSF proteome, including those associated with race and AD biomarkers are less well understood. Thus, we applied Weighted Gene Co-expression Network Analysis (WGCNA) to define trends in protein co-expression across 1840 CSF proteins in all individuals. These parameters identified 14 modules

**Figure 3.2. Differential expression of Caucasian and African American CSF proteomes in AD.** Volcano plot displaying the log<sub>2</sub> fold change (FC) (x-axis) against one-way ANOVA with Tukey correction derived -log10 p-value (y-axis) for all proteins (n=1840) comparing AD versus Controls for Caucasians (**A**) and African Americans (**B**). Cutoffs were determined by significant differential expression (p<0.05) between control (CT) and AD cases. Proteins with significantly decreased levels in AD are shown in blue while proteins with significantly increased levels in disease were indicated in red. Select proteins were denoted and labeled by whether they were differentially expressed in both proteomes (yellow), in only the Caucasian proteome (green), or in only the African American proteome (purple). (**C**) Venn diagram illustrating the number of differentially expressed proteins (DEPs) that were uniquely changed in one proteome (green or purple) or changed in both proteomes (yellow) (**D**) The correlation between the fold change of all DEPs (n=402) across the African American proteome (x-axis) and the Caucasian proteome (yaxis) were strongly correlated (bicor=0.887, p=2.47e-136), regardless of whether the DEP was significant in one (green or purple) or both proteomes (yellow). (M), ranked by size, ranging from the largest M1, with 370 proteins to the smallest, M14, with 16 proteins (**Figure 3.3A**). Many of these modules were significantly enriched for brain-specific cell types (**Figure 3.3B**) as well as established brain gene ontologies (GO), cellular functions and/or organelles (**Figure 3.3C**). The three largest modules were associated with categories of "Postsynaptic Membrane" (M1), "Complement Activation" (M2), and "Extracellular Matrix" (M3) whereas M5 represented "Lysosome / Catabolism" and M6 "Gluconeogenesis". Other modules included those with GO terms linked to "Cell Morphogenesis" (M4), "Cell Redox / Proteasome" (M7), "Protein Polyubiquitination" (M8), "Angiogenesis / Cell Migration" (M9), "Synapse Assembly" (M10), Myofibril Assembly (M11), "Actin Cytoskeleton" (M12), "Kinase Signaling / Activity" (M13), and "Carbohydrate Metabolism" (M14).

Protein-based network analysis in AD brain tissue has shown that the cellular composition represents a major source of biological variance and that many of the network modules are enriched in proteins that are expressed by specific brain cell types (236; 237). To determine if a similar relationship exists with protein-based networks in CSF, we evaluated the overlap of proteins in each module with brain cell-type specific makers (**Figure 3.3B**), generated previously from cultured or acute isolated neurons, oligodendrocytes, astrocytes, endothelial, and microglia from brain (266; 267). The largest module, M1, was enriched with neuron/synaptic proteins (i.e., NPTX1, NPTXR, SCG2, VGF, NRN1, and L1CAM) and to a lesser degree oligodendrocyte proteins (i.e., IGSF8, VCAN, APLP1). Neuronal loss or the active secretion of neuronal proteins into the extracellular space could account for the presence of neuronal proteins in the CSF. The M4 module was also enriched for neuronal protein markers including RTN4R1, LINGO2, OLFM1, and PLXNA2, associated with "Nervous Systems and Cell Morphogenesis". Modules most enriched with microglia markers were M2 (i.e., C2, C3, C1RL, C1QA, C1QB, C1QC, LCP1, etc.) and M5 (i.e., HEXB, CTSZ, HEXA, CTSA, CTSB) consistent with a role in complement activation and lysosome function, respectively. Finally, endothelial markers were mainly overrepresented in

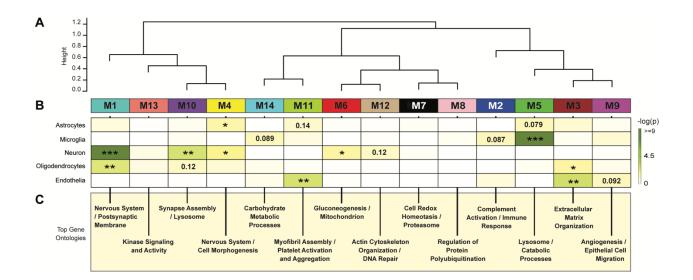

Figure 3.3: Network analysis classifies the CSF proteome into modules associated with specific brain cell-types and gene ontologies. (A) Weighted Gene Co-expression Network Analysis cluster dendrogram groups proteins (n=1840) into 14 distinct protein modules (M1-M14). (B) Cell-type enrichment was assessed by cross referencing module proteins by matching gene symbols using a one-tailed Fisher's exact test against a list of proteins determined to be enriched in neurons, oligodendrocytes, astrocytes, microglia and endothelia. The degree of cell-type enrichment increases from yellow to dark green with asterisks denoting the following statistical significance (\*p≤0.05; \*\*p≤0.01; \*\*\*p≤.001). Top gene ontology (GO) terms were selected from significant GO annotations.

modules M3 (i.e., NID2, ECM2, NID1, LTBP4, LAMA5, LAMC1), M9 (IGFBP7, F5, SDCBP, BGN) and M11 (FLNA, ANXA5, S100A11, MYL6) consistent with roles in extracellular matrix, angiogenesis and myofibril assembly, respectively. Thus, as seen in the network analysis of bulk proteome from human brain (236; 237), certain modules of co-expressed proteins in CSF were enriched with markers of specific brain cell-types. To further support this observation, we assessed the protein overlap between modules in CSF and modules from a recent large-scale consensus TMT-MS proteomic network of bulk human AD brain tissue (236). (Figure 3.4). Except for M9, M10 and M14, which had minimal overlap with the brain, all other modules (79% total) in the CSF network significantly overlapped with at least one of the 44 brain modules (B-M1 to B-M44). For example, there is overlap with CSF proteins in M1 "Postsynaptic Membrane" with several neuronal modules in the consensus brain network (B-M1, B-M4, B-M5, B-M10, and B-M15). In addition, M2 "Complement Activation" in CSF overlaps with modules in human brain associated with complement and immune response (B-M26 and B-M40), whereas M3 "Extracellular Matrix" strongly overlap with B-M27 in brain enriched with endothelial cell markers (Figure 3.4). Collectively, this supports that the co-expression in protein levels is, in part, shared between CSF and brain tissue, which could reflect changes in activation or phenotypes of specific brain cell types.

#### 3.2.4 CSF protein modules correlate to race and clinicopathological phenotypes of AD

We assessed module correlation to race, cognitive scores (MoCA), and the hallmark AD biomarkers A $\beta_{42}$ , tTau, and pTau<sub>181</sub>. The protein network resulted in three main groups/clusters based on module relatedness (**Figure 3.5A**). The first cluster (Group 1) was comprised of four modules (M2 "Complement Activation", M5 "Lysosome / Catabolism", M3 "Extracellular Matrix", and M9 "Angiogenesis / Cell Migration". Of these modules, M3 and M9 exhibited baseline racial differences in abundance levels (**Figure 3.5B**). Notably, the eigenprotein, which corresponds to

# Figure 3.4: Protein overlap between modules in CSF network and modules in a human AD brain network. (A) Protein module enrichment across the CSF and brain was assessed by matching gene symbols of proteins in each module from the CSF network against gene symbols for protein in each module from a human AD consensus brain network using a one-tailed Fisher's exact test The degree of enrichment increases from pink to light purple to dark purple with asterisks denoting the following statistical significance (\*\* $p\leq0.01$ and \*\*\* $p\leq.001$ ). (B) Similar to CSF, cell-type enrichment was assessed by cross referencing brain module proteins against a list of proteins determined to be enriched in neurons, oligodendrocytes, astrocytes, and microglia using a one-tailed Fisher's exact test. The degree of cell-type enrichment increases from yellow to green-yellow to dark green with asterisks denoting the following statistical significance (\*\* $<p\leq0.01$ and \*\*\* $p\leq.001$ ).

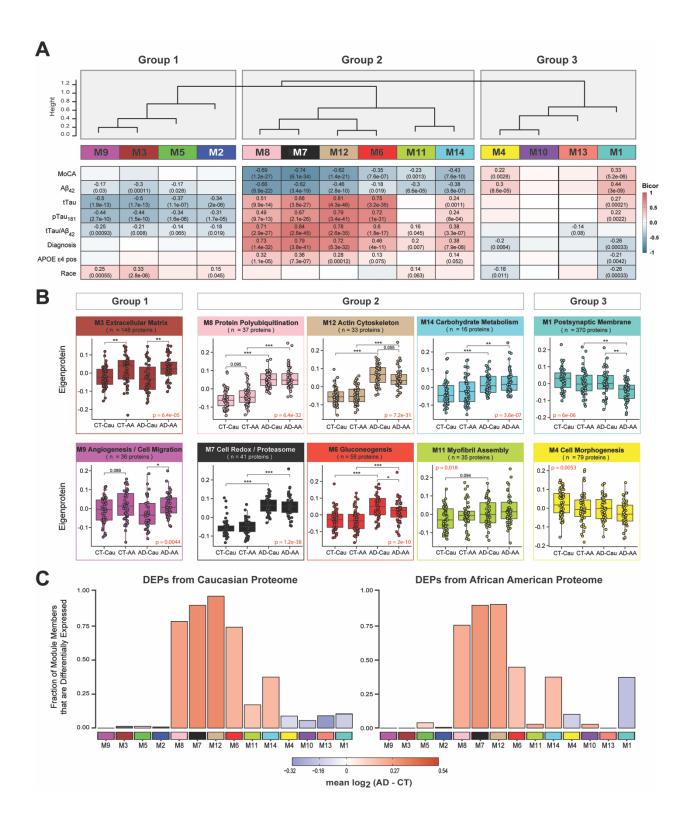

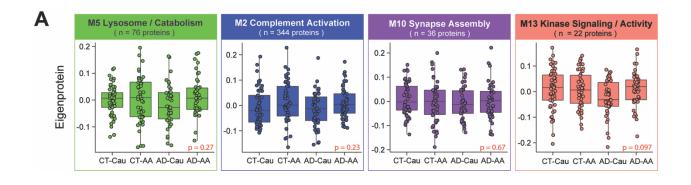

Figure 3.5: CSF protein modules correlate to race and clinicopathological phenotypes of AD. (A) Modules were clustered based on relatedness defined by correlation of protein coexpression eigenproteins (indicated by position in color bar). There were three main clusters in the network: Groups 1, 2 and 3. Biweight midcorrelation (bicor) analysis of module eigenprotein levels with diagnostic measures of AD, including MoCA score, immunoassay Amyloid-beta<sub>1.42</sub> (A $\beta_{42}$ ), total Tau (tTau), phosphorylated Tau<sub>181</sub> (pTau<sub>181</sub>), ratio measures of tTau/A $\beta_{42}$ , diagnosis, whether the sample has *APOE*  $\varepsilon$ 4 allele or not, and race. The strength of positive (red) and negative correlations are shown by a heatmap with annotated bicor correlations and associated p-values. (B) Eigenprotein values distributed by race and diagnosis of representative modules for each cluster. (C) Differential protein abundance AD samples compared to controls, by module with Caucasian proteome on the left and African Americans on the right. The height of the bars represents the fraction of module member proteins that DEPs compared to controls. The bars are color coded by heatmap for average log<sub>2</sub> difference in abundance, where red represents an increase in abundance in AD, and blue represents a decrease in abundance in AD. the first principal component of a given module and serves as a summary expression profile for all proteins within a module, were increased for these two modules in African Americans compared to Caucasians. Of note, these modules were enriched with endothelial cell markers (**Figure 3.3B**) which suggests that genetic ancestry and/or environmental differences influence expression or secretion of these cell-type markers. Similarly, M2 and M5, both of demonstrated enrichment for microglial markers, trended towards higher levels in both African American controls and AD (**Figure 3.3B and 3.6**), suggesting an accompanying immune response to the vascular alterations seen in modules M3 and M9.

The second cluster of modules (Group 2) was comprised of six modules (M8, M7, M12, M6, M11, and M14) that were all increased in AD (Figure 3.5A). These AD modules also demonstrated significant negative correlations to MoCA scores and, conversely, significant positive correlations to tTau/A<sub>β42</sub> ratio. With the exception of M11, these modules also exhibited positive correlations to APOE ɛ4 risk (Figure 3.5A). Interestingly, a hub protein of the M12 "Actin Cytoskeleton" module was Tau (MAPT). Consistent with CSF levels observed for Tau by immunoassay and TMT-MS (Figure 3.1B and C), the M12 eigenprotein had lower levels in African Americans, compared to Caucasians with AD, albeit not significant (p=0.055) (Figure 3.5B). Notably, M6 "Gluconeogenesis" was significantly lower in African Americans compared to Caucasians with AD, highlighting another module of CSF proteins that differed by race in AD (Figure 3.5A and B). This also indicated that the increased glycolytic signature of AD previously reported in CSF (237; 252) is higher in Caucasians with AD. Consistently, a greater proportion of increased DEPs in Caucasians with AD mapped to M6 compared to African Americans with AD (Figure 3.5C). In contrast, M7 "Cell Redox / Proteasome" and M8 "Protein Polyubiquitination", had the strongest correlations to  $tTau/A\beta_{42}$  ratio and cognition (**Figure 3.5B**), and both demonstrated strong, equivalent elevations in African Americans and Caucasians with AD (Figure 3.5B). This is consistent with an equivalent fraction of increased DEPs mapping to these modules in African American and Caucasians with AD (Figure 3.5C). Therefore, proteins in these

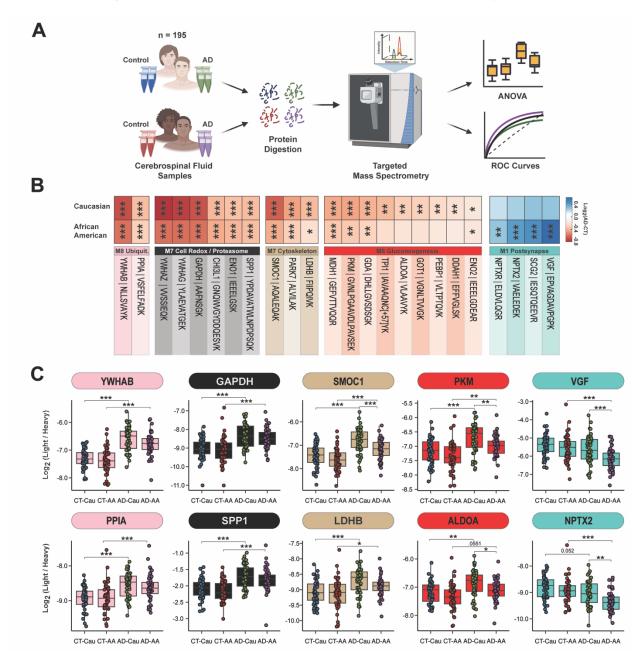

**Figure 3.6: Additional CSF network protein modules.** (**A**) Eigenprotein levels were distributed by race and diagnosis for remaining modules not shown in main Figure 4. This includes M5, M2, M10, and M13.

modules including 14-3-3 family members (YWHAZ, YWAHB, YWHAG, YWHAE) likely represent the best class of CSF AD biomarkers that are not influenced by race. M14 "Carbohydrate Metabolism" and M11 "Myofibril Assembly" were both elevated in both African Americans and Caucasians with AD (**Figure 3.5A and B**), yet to a lesser degree than M7 and M8.

The final group of modules (Group 3) contained two modules, M1 "Postsynaptic Membrane" and M4 "Cell Morphogenesis", that showed strong correlations to both race and AD diagnosis (**Figure 3.5A**). Both modules were i) decreased in AD compared to controls and ii) and were lower in African Americans compared to Caucasians. In addition, both M1 and M4 were enriched with neuronal markers and positively associated with cognitive MoCA scores (**Figure 3.5A**). Markedly, pairwise statistical analysis of eigenprotein levels for M1 across diagnosis and race revealed significantly lower levels in African Americans with AD (**Figure 3.5B**). To this end, most of the decreased DEPs in African Americans with AD mapped to M1 and to a lesser degree M4, whereas decreased DEPs in Caucasians with AD were equally distributed to M1, M4, M13 and M10 (**Figure 3.5C**). Notably, M10 and M13 within Group 3 did not show any differences with AD or race and did not significantly correlate with traits explored in this study (**Figure 3.5 and Figure 3.6**). Overall, network analysis effectively organizes the CSF proteome into protein modules that are strongly linked to hallmark AD biomarkers (A $\beta_{42}$ , tTau and pTau<sub>181</sub>) and cognition, which in some cases were also influenced by race.

## 3.3 Selected reaction monitoring validates protein alterations across Alzheimer's disease and race

To further validate these network findings, we used a targeted mass spectrometry method, selected reaction monitoring (SRM), with heavy labeled internal standards to measure CSF proteins across 195 of the 203 cases included in the discovery TMT-MS assays (**Figure 3.7A**). The proteins and corresponding targeted peptides were previously selected based on their robust

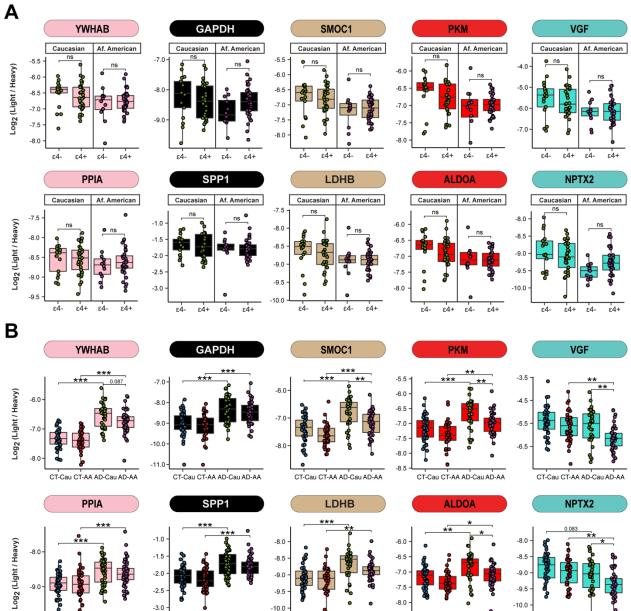

detection and significant differential expression in previous CSF discovery proteomic datasets

Part A of this figure was created with BioRender.com

## Figure 3.7 Validation of shared and divergent CSF protein levels across AD and race. (A) Schematic of experimental workflow for SRM analysis of cerebrospinal fluid proteome (B) Heatmap of peptides that were significantly differentially expressed between Control and AD Caucasians or African Americans. Stars are indicative of the level of significant difference (\*p<0.05; \*\*p<0.01; \*\*\*p<0.001) seen for each peptide between AD and Control within each race. Meanwhile the colors are indicative of the log<sub>2</sub> fold change (FC) of each peptide from Control and AD for each race where blue is indicative of the degree of decrease and shade of red is indicative of the degree of increase. (C) $Log_2$ abundance of peptides that mapped to modules of interest distributed by race and diagnosis. Pairwise significance was calculated using one-way ANOVA with Tukey adjustment.

(252; 268). We used pooled CSF samples of control, and AD cases as quality controls replicates (n=29 samples total) to assess technical reproducibility. Of the peptides targeted, 85 (mapping to 58 proteins) had a coefficient of variation of <20% in both the control and AD pools with no missing values (Appendix Tables 6.4). Following adjustments of co-variates (i.e., age and sex), peptide levels were highly correlated with protein levels measured by TMT-MS from the same samples (Appendix Table 6.6). If a protein was measured by more than one peptide the most correlated peptide to the TMT-MS protein level was selected for further analysis. The final peptide list can be found in **Appendix Table 6.7**. ANOVA analyses determined pairwise significance between the four groups (i.e., Control-Caucasians vs Control-African Americans vs AD-Caucasians vs AD-African Americans, Appendix Table 6.8). Figure 3.7B highlights peptides (n=24) that reached significance and that mapped to proteins in CSF modules associated with race and/or AD. Consistent with the TMT-MS protein measurements, proteins measured by SRM within M7 (GAPDH and YWHAG) and M8 (YWAHB and PPIA) had strong elevations (p < 0.001) in abundance in AD in both races, whereas proteins in M12 (SMOC1, PARK7, and LDHB) had a greater magnitude of change in Caucasians than African Americans with AD (for a list of all M12 members, see Supplemental Table 6). Similarly, a majority of the proteins measured by SRM in M6 (PKM, GDA, TPI1, GOT1, ALDOA and ENO2) were more increased in Caucasians than African Americans with AD (Figure 3.7B and C). Proteins in the synaptic M1 module (VGF, SCG2, NPTX2, and NPTXR) were significantly decreased in African Americans with AD compared to Caucasians (Figure 3.7B and C), again consistent with TMT-MS protein level abundance. Notably, African Americans with or without APOE £4 allele in the AD group had reduced levels of these CSF peptide biomarkers compared to Caucasians indicating that race and not APOE status was driving the difference in abundance (Figure 3.8A). Furthermore, these differences across race remained consistent even after removing patients with one or more comorbid condition (i.e., hypertension, diabetes, dyslipidemia, or cerebrovascular disease; Figure 3.8B).

CT-Cau CT-AA AD-Cau AD-AA

**Figure 3.8. Stratification of SRM CSF protein measurements by APOE genotype and comorbidity.** (**A**) Within each race, protein levels for were not affected by APOE ε4 genotype for YWHAB, GAPDH, SMOC1, PKM, VGF, PPIA, SPP1, LDHB, ALDOA, and NPTX2. (B) Within each race, protein levels were not affected by patient co-morbidities (hypertension, diabetes, dyslipidemia, or cerebrovascular disease) for YWHAB, GAPDH, SMOC1, PKM, VGF, PPIA, SPP1, LDHB, ALDOA, and NPTX2.

Finally, a receiver operating characteristic (ROC) curve analysis was performed to assess the performance of each peptide biomarker in differentiating controls and AD by race (Figure 3.9 and Appendix Table 6.9). We generated an area under the curve (AUC) for AD in African American and Caucasian individuals for each protein biomarker (considered separately in each race). As expected, proteins mapping to M8 and M7 including 14-3-3 proteins (YWHAB, YWHAG and YWHAZ) were equally able to discriminate AD from control irrespective of racial background. Notably, despite having lower levels in African Americans with AD compared to Caucasians with AD, only a modest improvement in the AUC for SMOC1 was observed for classifying AD in Caucasians AUC=0.8255 (p=1.71e-08, CI=0.7421-0.9090) compared to African Americans AUC=0.7618 (p=4.12e-06, CI=0.6660-0.8576). Similar findings were observed for another M12 protein, LDHB, as well as M6 proteins PKM and ALDOA. However, the M1 protein VGF was only nominally significant at classifying AD in Caucasian AUC=0.6030 (p=0.0406, CI=0.4887-0.7173), vet highly significant in African Americans AUC=0.7593 (p=5.03e-06, CI=0.6634-0.8552). Similar results were observed for other synaptic M1 proteins, NPTX2 and SCG2, whereas NPTXR showed only a modest improvement in the AUC between African Americans compared to Caucasians with AD (Figure 4.9 and Appendix Table 7.15). Collectively this supports a hypothesis that African Americans with AD have lower levels of a subset of neuronal biomarkers compared to Caucasians with AD.

**Figure 3.9: ROC analysis evaluated CSF protein classification of AD by race**. (A) YWHAB, PPIA, GAPDH, and SPP1 had similar performance in classifying Caucasians and African Americans with AD (B) SMOC1, PKM, LDHB and ALDOA showed modest improvement in the AUC for Caucasians with AD compared to African Americans with AD (C) VGF, SCG2, and NPTX2 were better classifiers for AD in African Americans compared to Caucasians, whereas NPTXR showed modest improvement in classification of AD in African Americans. All protein AUCs with p-values and confidence internals (CI) are provided in **Supplemental Table 15**.

#### **CHAPTER 4: DISCUSSION**

Segments of this discussion were originally published in *Molecular Neurodegeneration*:

Modeste, E.S., Ping, L., Watson, C.M. *et al.* Quantitative proteomics of cerebrospinal fluid from African Americans and Caucasians reveals shared and divergent changes in Alzheimer's disease. *Mol Neurodegeneration* **18**, 48 (2023). <u>https://doi.org/10.1186/s13024-023-00638-z</u>

Here we performed an unbiased quantitative analysis of the CSF proteome to identify protein biomarkers reflective of underlying AD brain physiology that are shared or unique across race. Using network analysis, we organized the CSF proteome into 14 modules of proteins with highly correlated levels in CSF. Notably, these modules were associated with cell-types and biological pathways in brain and largely overlapped with modules from a consensus human AD brain proteomic network (236). Consistent with previous findings (261; 262), we also show that Tau levels were lower in African Americans with AD compared to Caucasians in CSF. Notably, Tau mapped to a CSF module enriched with other related neuronal/cytoskeletal proteins with a magnitude of increase greater in Caucasians than in African Americans with AD. This indicated that an entire network of proteins, rather than a single protein, is changing differently with disease between these two racial groups. In contrast, CSF modules which included 14-3-3 proteins, were elevated equivalently in both African Americans and Caucasians with AD, suggesting similar changes in pathophysiology. Lastly, a module enriched with neuronal/synaptic proteins including VGF, SCG2, and NPTX2 was significantly lower in African Americans than Caucasians with AD. These findings were consistent when VGF, SCG2, and NPTX2 levels in CSF were measured using SRM analysis, which also showed significantly better classification of African Americans with AD compared to Caucasians. Together, our findings suggest that there are likely distinct mechanisms underlying the abundance and/or secretion of neuronal markers including Tau and VGF that differ by race. Collectively, these data underscore the need for further investigations into how AD biomarkers and underlying physiology vary across different racial backgrounds.

## 4.1 Protein co-expression between the brain and CSF reflects the intricate role of CSF in brain function and health.

In a previous study we performed unbiased TMT-MS on a small discovery cohort of control and AD CSF samples (n=40) and mapped these proteins onto a human AD brain co-expression network, revealing that approximately 70% (n=1936) of the CSF proteome (N=2,875) overlapped

with the brain network (N=8817) (252). Additionally, it was found that 271 of the proteins that were significantly altered in the CSF were also differentially expressed in the brain (245). The increased sample size in this study afforded the opportunity to extend beyond this analysis by constructing an independent co-expression network on the CSF proteome and assessing its overlap with modules in a consensus brain network. This analysis revealed a strong overlap between CSF and brain modules, with 11 of the 14 CSF modules significantly overlapping with one or more brain modules, further supporting that protein co-expression in the brain is conserved in the CSF. These findings are not surprising considering the close relationship between CSF and brain. It is already known that substrates needed by the brain can be transported from the blood through the choroid plexus into the CSF, and then from the CSF into the extracellular space within the brain (269). Inversely, CSF aids in the removal of brain metabolism waste products, such as glycosylated proteins, excess neurotransmitters, and other unnecessary molecules, from the cerebral region (269). As a result of these exchanges, changes in brain chemistry can ultimately influence CSF composition, allowing the CSF to mirror neuropathological changes in the brain. Our studies suggests that the observed changes in CSF are mainly driven by cell-type alterations, as most CSF modules were enriched with either neuronal (M1, M4, M6, M10 and M12), glial (M2, M5, and M14), astrocyte (M4 and M5), oligodendrocyte (M1 and M3), and endothelial-specific markers (M3, M9, and M11). The remaining modules that did not exhibit enrichment with cell type markers represented processes related to cellular signaling (M13) and degradation pathways (M7 and M8), including kinase signaling and activity, protein polyubiquitination, and cell redox/proteasome processes. This reflects another crucial function of the CSF, which is aiding in the clearance of waste products from the brain (269). In conclusion, network analysis of the CSF underscores the intricate relationship between CSF and brain biology in AD, revealing shared protein alterations and cell-type enrichments across both compartments. These findings support our understanding of CSF as a conduit for biomarkers of neuropathological changes in AD and provide insights into the underlying mechanisms driving early disease progression.

4.2 CSF network analysis indicated differences in endothelial markers across race, irrespective of disease, yet there is insufficient evidence to indicate that these differences stem from variations in endothelial damage.

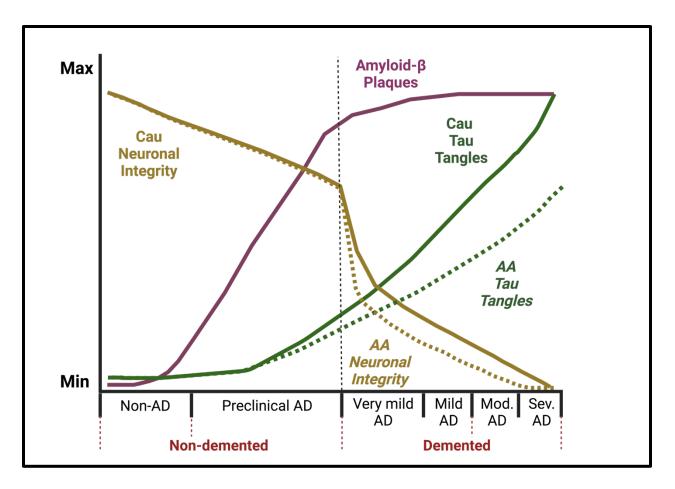

In regards to the CSF network biology that differed by race, it's noteworthy that modules significantly enriched in endothelial proteins (M3 and M9) were elevated in African Americans across both control and AD individuals. M3 is primarily comprised of extracellular matrix (ECM) proteins, and ECM proteins make up the dynamic network of macromolecules providing structural support for cells and tissues. In the brain, ECM proteins are vital for maintaining the integrity of the blood-brain barrier (BBB) and neurovascular units (262-265). ECM proteins in the BBB are crucial for preserving brain tissue homeostasis by preventing the entry of unwanted cells and molecules and by removing metabolic waste. Additionally, ECM proteins within the neurovascular unit play a crucial role in regulating cerebral blood flow (CBF), ensuring sufficient blood supply to meet the demands of neurons (266; 267). Consequently, malfunctioning ECM proteins in the brain can result in compromised function of both the BBB and neurovascular units. Notably, two critical vascular changes associated with AD are the breakdown of the BBB (270; 271) and compromised CBF (272). Moreover, these dysfunctions can subsequently trigger increases in proteins associated with angiogenesis, the process of forming new blood vessels. Pathological angiogenesis has been significantly implicated in perpetuating AD by fostering further AB generation, which, in turn, can exacerbate BBB dysfunction and impaired CBF (273). It is noteworthy that the M9 module is enriched with proteins involved in angiogenesis and is also elevated in African Americans compared to Caucasians, irrespective of disease status. In conclusion, the increased presence of endothelial proteins among African Americans implies that vascular differences may play a role in the heightened susceptibility to AD within this demographic. This highlights the necessity for additional investigation into how differences in vascular health between racial groups may impact the susceptibility and advancement of AD.

Currently, growing evidence suggests that endothelial dysfunction plays a significant role in the cognitive decline associated with AD (268), raising the question of whether the elevated levels observed in African Americans could indicate such injury. Furthermore, endothelial impairment is common among individuals with atherosclerosis, hypertension, diabetes, and chronic kidney disease (266), conditions that are more prevalent in the African American population. Several studies have already highlighted plausible biomarkers for endothelial dysfunction (268). Osteopontin (OPN) (269; 270) and cell adhesion molecules like VCAM1 and ICAM1 (271-273) are indicators of vascular inflammation, while albumin (ALB) (274-277), soluble platelet-derived growth factor receptor-beta (sPDGFR<sub>β</sub>) (278), vasoactive molecules such as atrial natriuretic peptide (ANP), adrenomedullin (ADM), and B-type natriuretic (BNP) (279; 280), metalloproteinases (MMPs) (281-286), and blood coagulation proteins like fibrinogen (FGB) (287) and plasminogen activator inhibitor-1 (PAI1) (288) reflect vascular damage. Additionally, growth factors such as vascular endothelial cadherin (VGEF) (289-297), angiogenin (ANG) (292; 298), and angiopoietin-1 (ANG1) (299) have been shown to be altered during endothelial injury. When overlaying these indicators over proteins assigned to module memberships in the CSF proteome, it was found that only one of these markers, ANG, mapped to M9 or M3. Most of the other proteins identified within this CSF proteome (ICAM1, CDH5, ALB, MMP2, FGB) mapped to the blue module, which remained largely unchanged across both control and AD groups as well as between races. One exception was sPDGFR<sup>β</sup>, which mapped to the M1 module. Increased CSF levels of sPDGFRβ have been linked to BBB breakdown in individuals with mild cognitive impairment (274). It has also been demonstrated that heightened levels of sPDGFRβ correlate with cognitive decline in the early stages of AD (275). Nevertheless, the module members of M1 decrease with disease progression, and even exhibit even greater declines in African Americans. Remarkably, alongside being identified as elevated in AD, sPDGFR<sup>β</sup> levels have been noted to be lower in African Americans compared to Caucasians (276). Together, the data is insufficient to support that the elevated levels of endothelial markers observed in African Americans in this

study are indicative of endothelial impairment or injury. However, this study still indicates fundamental differences in the levels and/or activation states of cells residing in the vasculature between African Americans and Caucasians. Whether this biological difference is observed in brain tissues or relates to a higher incidence of vascular health disparities between African Americans and Caucasians (300) requires further investigation. Genomic analysis could prove invaluable in this endeavor, shedding light on whether these elevations are attributable to genetic variations. Furthermore, it is crucial to consider the influence of social determinants of health, such as education, socioeconomic status, and exposure to adversity and discrimination, on overall health, and thus AD risk and progression. Future studies should aim to integrate CSF protein levels with vascular risk factors, environmental metrics, and sociodemographic data to better elucidate the underlying racial differences in the CSF proteome. This holistic approach will help uncover the complex interplay between genetic, environmental, and social factors that contribute to AD pathogenesis and inform on the development of targeted interventions for diverse populations.

## 4.3 Unveiling the interplay between neuronal alterations in AD and the role of the CSF in mirroring cognitive decline

The current biological framework for the pre-symptomatic stages of AD is based on the presence of Aβ deposition (A), tauopathy (T), and neurodegeneration (N) also termed the A/T/N framework (277). CSF remains the gold standard for A/T/N biomarkers of neurodegenerative disease as it maintains direct contact with the brain and reflects biochemical changes in amyloid (**Figure 4.1, purple line**), Tau (**green line**) and neurodegeneration (**yellow line**). A strength of our study was the balanced nature of African American samples, which offered the ability to examine racial differences in both cognitively normal controls with individuals diagnosed with AD. Our mass spectrometry measurements of Tau strongly correlated with immunoassay levels

Created with BioRender.com

Figure 4.1: Hypothesized time course differences in neuropathological and clinical changes based on biomarker alterations between Caucasians and African Americans with Alzheimer's disease. In Alzheimer's disease (AD), the conversion from a non-demented to demented state is associated with a buildup of amyloid-beta ( $A\beta$ ) plaques (purple line), the accumulation of neurofibrillary Tau tangles (green line), and neuronal and synaptic loss (yellow line). Based on biomarker studies, the trajectory of change for the accumulation of Tau and the subsequent neuronal loss differs in African Americans with AD (dashed lines).

measured on the Roche Elecsys platform reinforcing measurements made by TMT-MS. Increased Tau in CSF is considered to result from neurodegeneration, however, it has also been shown to be increased in early pre-symptomatic disease stages when neurodegeneration is limited (277; 278) (Figure 4.1, preclinical AD). Recently, Tau CSF levels have been linked to enhanced synaptic plasticity where high levels of CSF Tau levels can be reflective of increased neuronal plasticity (279). Network analysis revealed a cluster of proteins, M12, along with another module, M6, exhibiting similar fluctuations in levels as Tau across racial groups, suggesting the involvement of other proteins that may function similarly to Tau in early disease synaptic plasticity. Other proteins that have been associated with synaptic plasticity include Calcium/calmodulindependent protein kinase II (CaMKII), cAMP-response element binding protein (CREB), Protein Kinases A and B (PRKAC1A and PRKAC1B), and growth-associated protein (GAP43) (269-273). Interestingly, all these proteins, including CAMK2A, CAMK2B, PRKAC1A, PRKAC1B, and GAP43, were categorized within the M6 module, indicating the potential association of other proteins within this module in synaptic plasticity. Further exploration of these proteins and their implications in racial disparities could provide valuable insights into AD pathogenesis and aid in developing targeted interventions.

Significantly, a considerable portion of synaptic proteins identified in this study aligned with M1 and M4. These modules demonstrated an overall decrease in levels with cognitive decline. We, also, observed that African Americans in this study had on average lower levels of neuronal markers mapping to M1 and M4 in the network, which are reduced in AD. Paradoxically, African Americans also have lower levels of neuronal proteins in M6 and M12, which all increase in AD. Consistent with this observation, in a recent CSF proteomic study in an asymptomatic Caucasian European population stratified by Tau CSF levels, individuals deemed to have high Tau levels maintained levels of M1 post-synaptic proteins (CADM3, NEO1, NPTX1, CHGB, PCSK1, NEGR, L1CAM, PTPRN, CACNA2D, PAM, VEGFA, NBL1 etc.) compared to individuals with lower Tau levels (279). This observation is analogous to differences we see between African

Americans and Caucasians with AD. M1 members VGF and NPTX2, strongly correlate to antemortem cognitive measures (280-282) and VGF and NPTX2 have been nominated as biomarkers of neurodegeneration (N) as their CSF levels enhance prediction of MCI to AD (282-284). Collectively, this would suggest that a specific sub-group of individuals with AD, including African Americans, have a higher burden of neurodegeneration (N) despite low CSF Tau levels (**Figure 4.1**, **dashed lines**). Longitudinal studies examining changes in CSF levels of neuronal proteins and other module constituents over time, with a specific focus on diverse racial populations, will be essential. By tracking the temporal patterns of protein biomarkers, researchers can gain a better understanding of critical timeframes for potentially delaying cognitive decline associated with the disease and addressing racial disparities in disease progression. Moreover, longitudinal studies can offer insights into the efficacy of therapeutic interventions and assist in devising personalized treatment approaches.

Collectively, these data suggest that there are likely distinct mechanisms responsible for the dysregulation of neuronal proteins, resulting in two separate pools of neuronal proteins that either go up or down with disease in CSF. Further investigations should be conducted to explore the distinct mechanisms that contribute to the differences in abundance and/or secretion of neuronal markers such as Tau and other proteins increased in AD CSF like CAMK2A, SNCB, and SYN1, In conjunction, the interplay between the neuronal markers that increase and neuronal markers that decrease with disease like VGF, NPTX2, and SCG2, which have also been found to differ by race, should be further explored.

#### 4.4 Future directions

Although a strength of our study was the large number of African Americans included, there are several limitations that should be noted. First, we acknowledge that many of the protein changes we observe in the CSF across race could be due to ancestral or genetic differences (285; 286). There were no genetics *a priori* performed on these study participants to confirm

enrichment of African vis a vis European ancestry (287) as we stratified race solely by selfidentification. Future studies, which include the integration of genetics and protein abundance to define protein quantitative trait loci (pQTL) will be necessary to resolve which proteins are under genetic control across race (288-290). It is noteworthy that the expression level of most modules which differed between racial groups were decreased in African Americans relative to Caucasians. Upon integration with whole genome profiling of larger cohorts, these patterns may help in the future to identify pQTLs or other mechanisms influencing synthesis and turnover of proteins that differ by race. Additionally, only a few studies to date have investigated proteomic difference by race in AD (291; 292), which have predominately focused on brain tissues and not on the scale of this current study. However, a major initiative of the Accelerating Medicine Partnership (AMP)-AD partnership (293) is to increase the number of diverse tissues included in multi-omic analyses, which will complement data generated from these previous studies. To support this effort, 81 brain tissue samples, obtained from Emory's Alzheimer's Disease Research Center, were prepared for future analysis. These samples have since been integrated with brain tissues from other AMP-AD partners, broadening the scope of the large-scale brain analyses (294; 295). Furthermore, despite the well documented differences in the quality of education, higher rates of poverty, and greater exposure to adversity and discrimination that increase risk for dementia (214; 215), these metrics were not captured on the participants in this study. Integrating CSF protein levels with vascular risk factors, and other environmental metrics in larger cohorts may help better resolve some of the underlying racial differences in the CSF proteome. Finally, in this study we adjusted for co-factors such as age and sex to pinpoint changes that are most likely to be associated with race and AD. Sex and age have an impact on the abundance of CSF Tau and other protein levels (296). Therefore, future studies that assess the interactions between, age, sex and race will be informative. Nevertheless, this study reveals an impressive view of protein co-expression in AD CSF across race, which provides new insights into the pathways underlying cell-type changes and further evidence that race may mediate these in AD. Future

directions in AD research should aim to unravel the distinct mechanisms underlying racial differences in AD biomarkers and underlying physiology. Integrating genetic, proteomic, and sociodemographic data, along with longitudinal investigations, will contribute to a more comprehensive understanding of AD pathogenesis and facilitate the development of targeted interventions for diverse populations affected by AD.
